Of the *Second Period*, or *Norman Style*, many more examples remain than of those in the *First Period*; as in the nave, aisles, transept, and west front of Tewkesbury; the nave and west front of Malmsbury; Wimborn minster; Dunstable; St. Cross in Hampshire; Romsey in the same county, &c. Also in the cathedrals of Ely; western towers, and nave, choir, and round tower, called Becket's Crown, at Canterbury; nave and choir at Norwich; transept and choir at Hereford, chapterhouse at Chester; presbytery at Chichester; transept at Peterborough, &c. The characteristics of this style are, *arches*, generally semicircular, as in the diagram (3) here given of the nave of Gloucester cathedral, and of much larger dimensions than those of the preceding periods; their ornaments less minute. They are sometimes without ornament at all, and their soffits are always plain. In the second tier two small equal arches are comprised under one larger one, with a column between, from which they spring, thus (4): — In the third tier there are generally three together, the central one being higher and wider than those on the sides, and usually opened for a window. The three, however, only occupy a space equal in width to the lower arch. The arches, which serve for the decoration of entrance doorways, are richly ornamented with mouldings, foliage, representations of men and animals of grotesque forms fantastically put together. The pointed arch began to creep in about the end of this period, though but sparingly; and it may sometimes be seen capriciously intermixed with the semicircular arch, and alternating with it: when these appear they are usually sharp-pointed. — *Columns*. These are of large diameter compared with their intervals; the shaft is circular, hexagonal and sometimes octagonal on the plan; fluted, lozenged, reticulated, and otherwise sculptured. Sometimes they are square on the plan, and then they are accompanied by portions of columns or pilasters applied to them. Sometimes four columns are connected together, with or without angular pieces. They are much higher in proportion to their diameters than the Saxon columns above described; and though their capitals are not unfrequently quite plain, they are more commonly decorated with a species of volute, or with plants, flowers, leaves, shells, animals, &c. The bases stand on a strong plinth adapted on its plan to the shape of the combined forms. — *Windows*. These are still narrow, and semicircular-headed; but they are higher, and often in groups of two or three together. — *Ceilings* always of timber, except in crypts; in which they are vaulted with stone, with plain groins, frequently moulded, and with ornamented edges; but they are universally without tracery: the White Tower of London, however, affords an example of a centre aisle covered with vaulting.—The *walls* are of extraordinary thickness, with but few buttresses, and those of small projection, usually without ornament. — The *ornaments* employed were, the chevron or zigzag moulding (5); the embattled frette (6); the triangular frette (7); the nail head (8); the billet (9); the cable (10); the wavy (11); the nebuly (12); and some others. Many of these were used in the preceding period, as well as many which have received no names. Ranges of small arches also appear; these rest on brackets, sometimes with carved heads, along the upper part of a building, just below the eaves or battlement, and have received the name of a corbel table. (13) — *Plans* in this period are always with transepts and a tower at the intersection, rather loftier than before, and without spires; there are usually tiers of arches one above the other, and the eastern ends are semicircular. Though much of the Saxon style is retained, there is, from the larger dimensions of the edifices of this period, a much more impressive air of magnificence than has hitherto appeared. Indeed, the larger dimensions alone have by some been thought to be the only criterion for distinguishing the Norman and Saxon styles; but this cannot be depended on, inasmuch as many of the former buildings are of small extent.

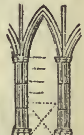
The *Third Period*, or *Early English Style*.—It was not till towards the close of the reign of Stephen, that the first transition from the Anglo-Norman style appears to have taken place. As we have before hinted, it is discoverable in the arch, which, from being semicircular, became pointed; a circumstance, though often investigated by antiquaries, still in obscurity. There is, however, another remarkable feature exhibited in the transition; the transformation, namely, of single massive pillars into clusters of small ones. Specimens of this style may be seen in the conventual edifices of Westminster Abbey, Tintern Abbey in Monmouthshire, Ripon and Beverley minsters in Yorkshire; and in the cathedral of Lincoln, the nave and arches beyond the transept; in York, the north and south transepts; in Wells, the tower and western front; in Ely, the presbytery; in Oxford, the chapterhouse; in Worcester, the transept and choir; and in Salisbury throughout. The characteristics of the style are, *arches* sharply pointed, and lofty in proportion to their span. In the upper tiers two or more are comprised under one, and finished with trefoil (14), or cinquefoil (15) heads, instead of points. — The *columns* (16) on which the arches rest are extremely slender in respect of their height, and usually consist of a central shaft surrounded by several smaller ones. The base assumes the general form of the cluster, and the capital is often decorated with foliage of extremely elegant formation. —*Windows* tall, narrow, and shaped at top like the head of a lancet; hence some writers, among whom Dallaway, have called this style the *lancet* Gothic. They are divided by one or at most two plain mullions, finished at their upper extremities with some simple ornament, such as a trefoil. —*Roofs* are high-pitched, and the *ceilings* vaulted, affording the first examples of arches with cross springers only, which, after a short period, diverged into many more, rising from the capitals of the columns, and almost overspreading the whole of the vaulting; the longitudinal line which reigned along the apex of the vault being decorated with bosses of flowers, figures, and other fancies.—The *walls* now lessen in thickness; but they are strengthened externally with buttresses, leaning as it were against them, for the purpose of counteracting the thrust exerted by the vaults

(14)

(15)

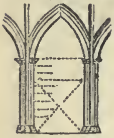
(16)



of the ceilings, which the walls and piers could not by their own gravity resist. The buttresses are, moreover, aided in their office by being surmounted with pinnacles, adorned with crockets at their angles, and crowned with a finial flower. — The *ornaments*, though numerous, are simple and elegant. The mouldings have not the variety found in the preceding period, being usually cut into a combination of leaves and flowers, placed commonly round the sides of arches, and especially of windows; but the columns are sometimes completely, as it were, embroidered with them. The spandrels of the arches are often covered with trefoils, quatrefoils, cinquefoils, roses, mullets, bosses, pateræ, &c. The pinnacles of shrines are high and acutely formed, often with niches under them containing statues; similar niches are also frequently used on the west and eastern fronts, their heads being extremely sharp. These ornaments, however, are not so profusely used in large as in small edifices, or in parts added to old ones. — The *plans* are generally similar to those of the *Second Period;* but the towers rise to a great height, and lanterns and lofty spires are very frequent accompaniments to the structure. In the transition from the second to the third style, it will naturally occur to the reader that the architect left one extreme for another, though it has been contended that the latter has its germ in the former. Be that as it may, the period of which we are now speaking was undoubtedly the germ of the succeeding styles by no very forced or unnatural relationship.

The *Fourth Period*, or *Ornamented English Style*.—Examples of this style are, the Chapel of Merton College, Oxford; New College Chapel in the same city; St. Stephen's Chapel, Westminster, so injured by the conflagration of the houses of parliament as to be now no longer in existence; St. Mary's, in York; choir of Tewkesbury, in Gloucestershire; Magdalen College, Oxford; Eton College Chapel, Bucks; and the Beauchamp Chapel at Warwick: also in the cathedrals of Exeter; nave and choir of

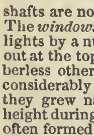
(17)



Litchfield throughout; naves of Worcester and York; spire and tower of Norwich; spire of Salisbury; nave and choir of Bristol; the Lady Chapel and Louvre at Ely; choir of Gloucester; Bishop Beckington's additions at Wells and at Lincoln, from the upper transept to the great east window. Its *characteristics* are, that the *arches* are less acute, changing in form, and more open. (17) In the *columns* the central and detached shafts are now brought into one general combination.— The *windows* are not only larger, but divided into several lights by a number of mullions, which constantly branch out at the top into leaves, flowers, wheels, fans, and numberless other forms. Though, however, these expanded considerably during the reigns of the two first Edwards, they grew narrower and sharper in proportion to their height during the reign of Edward III., when the head was often formed of lines scarcely curved above the haunches. The eastern and western windows were of large dimensions, and their glass splendidly painted. — The *ceilings* were constructed with vaulting of very highly decorated parts, whose principal ribs, spreading out from their springings on the imposts, covered the whole surface with tracery, much subdivided, and ornamented with beads, bosses, and a multitude of other devices, which were elaborately painted and gilt. — The *ornaments* are not so pure in line as in the previous style; but they are more varied and studied. Niches covered with tabernacles, for the reception of statues, every where abound; tiers of ornamental arches; pinnacles, not so lofty and tapered, but adorned with leaves and crockets, with much sculpture, painted and gilt, constantly occur; as also screens, carved stalls, panelled ceilings, and other ornaments in carved and painted wood.

The *Fifth Period*, being the *Florid English* or *Tudor Style* (18), is very completely exhibited in Henry the Seventh's Chapel at Westminster, King's College Chapel

(18)



at Cambridge, and St. George's Chapel at Windsor,—edifices well known to most persons in this country. Examples are to be found also in the Lady Chapel of Gloucester Cathedral, Alcocke's Chapel at Ely, the exterior of the choir at Winchester, the Lady Chapel at Peterborough, and the north porch at Hereford. In the Tudor style, it seems as though this species of architecture having culminated, was now destined to set in a blaze of uncontrolled splendour of ornament. Simplicity was superseded by the dazzle of minute decoration, which was exhausted by the caprice of its inventors. It has therefore as well received the name of *Florid*, as its other name of *Tudor;* the latter from having been introduced and carried to its utmost pitch during the power of the family of that name. Its *arches* are universally flat and wide in proportion to their height.—The *windows* are much more open than in the last, flatter at the top, divided in the upper parts by transoms, which are almost constantly crowned with miniature embattled work.—The *ceiling* spreads out into such a variety of parts that the whole surface seems covered with a web of delicate sculpture or embroidery thrown over it; and from different intersections of this ribbed work clusters of pendent ornaments hang down, as Mr. Millers observes, like "stalactites in caverns." The *flying buttresses* are equally ornamented, and the external surfaces of the walls are one mass of delicate sculpture. The *ornaments*, as may be deduced from what we have above noticed, are lavish and profuse: fretwork, figures of men and animals, niches and tabernacles, accompanied with canopies, pedestals, and tracery of the most exquisite workmanship, carried this style to the summit of splendour, and perhaps had no small share in producing the extinction it was doomed to undergo.

The beautifully timber-framed roofs, of which many examples still exist, appear to have originated, as applied to great halls, about the reign of Edward III. About 1400 they were employed in churches, wherein prior to that date stone vaulting appears to have been more common. The Norman castles had their keeps and halls vaulted with stone, as was the case in those in North Wales built by Edward I.

Our limits preclude us from adverting to many fine specimens of ecclesiastical architecture in Scotland; but the abbeys of Melrose and Kelso, founded by David I., as well as those in Dryburgh and Jedburgh, all in Roxburghshire, show that the art was carried to as great perfection north of the Tweed as in the southern parts. Roslin and Holyrood Chapels, for richness and variety of ornamental carvings (the first erected by Sir William St. Clair), cannot be exceeded. Its plan is without parallel in any other specimen of the fifteenth century. The latter was finished by James, the second of that name, in 1440; and is a beautiful specimen, with flying buttresses, more ornamented than any even in England.

It would be impossible here to enumerate the palaces and private Gothic buildings of this country, of which parts still exist in the remains of the ancient palace at Westminster, Eltham, Kenilworth Castle, Hampton Court, and in many other places. A desire to renew it has appeared in this country of late years; but we doubt whether such will be attended with success. The habits of the people, one of the principal stimulants in architectural style, seem to us rather out of joint for the purpose. The following list exhibits the dimensions of the different cathedrals in England, rearranged from the Rev. Mr. Dallaway's *Discourses upon Architecture*.

ENGRAILMENT. The ring of dots round the edge of a medal.

ENGRAVING. (Sax. ᵹnafan, *to dig.*) The art of producing by incision or corrosion designs upon blocks of wood, plates of metal, or other materials, from which impressions or prints upon paper or other soft substances are obtained by pressure. Engraving, as an art, seems to have nearly the same relation to design and painting as typography bears to written language; and its utility and great importance must be obvious to every one from its capability of giving a boundless circulation to representations of the most valuable examples of the arts and of objects connected with science. By some authors it is placed among the representations called monochromes (μονοχρώματοι). Xylography, or wood-engraving, was the earliest method practised; but its origin is involved in obscurity. If we might rely on Du Halde (*Description, &c. de l'Empire de la Chine*, 4to. 1736), it is possible that it was known in China 1120 years before Christ; though we think its invention is of a much later period, as the Chinese were not acquainted with the art of making paper till 95 B.C. It has been stated that this art was introduced into Europe from China, through the intercourse of the

Venetian merchants with its inhabitants; for it is proved that engraving on wood had been practised in that part of Italy which borders on the Adriatic as early as the 13th century. The first wood engravings in Europe of which any thing is known with certainty were executed in 1285, by a brother and sister of a noble family of the name of Cunio. They represent the actions of Alexander; and though doubts of their authenticity are expressed by Heinecken, Mr. William Young Ottley, the author of the elegant and learned *History of Engraving*, to which we are much indebted, thinks otherwise. But for the accidental discovery by a Venetian architect of the name of Temanza of a decree of the magistracy of Venice, in 1441, we might have been without positive proof of the practice of the art in Italy previous to 1467, and the Germans might still have continued to claim the honour of its introduction into Europe. This decree, dated 11th October, 1441, states in substance that the art and mystery of making cards and printed figures had fallen to decay, owing to their extensive importation; and in order that the native artists might find encouragement rather than foreigners, it was ordered that no work of the said art, printed and painted on cloth or paper, — viz. altar-pieces or images and playing cards, and whatever other work of the said art is done with a brush and printed, — should be allowed to be brought into the city, on pain of forfeiting the works, besides a pecuniary penalty. This decree plainly indicates that wood engraving was practised in Venice as early as the commencement of the fifteenth century. In Germany and the Low Countries, the early block books seem to have existed as early as 1420, and to have given Guttenburg the hint for using moveable types. At Rome, in 1467, a work intituled *Meditationes Johannis de Turrecremata*, issued from the press of Ulric Han, embellished with wood engravings, in which the design and execution of an Italian artist are evident. The decorations of the work of Valturius by Matteo Pasti, of Verona, published five years afterwards, exhibit considerable spirit and accuracy; and before the end of the fifteenth century the art had been carried to great perfection, as may be proved by the delicacy and purity with which the designs are engraved in the celebrated Hypnerotomachia of Colonna. (*See* ARCHITECTURE.) At this period, however, the discovery of copper-plate engraving had been made, and to this the more ancient art yielded place. Maso Finiguerra, a goldsmith and sculptor of Florence, and pupil of Masaccio, about the middle of the fifteenth century, seems from the most authentic accounts to have been the person to whom the world is indebted for the discovery. In his time, and for a considerable period previously, it was the practice to decorate church and other plate with works in *niello*, which were designs hatched with a steel point upon gold or silver, then engraved with the burin, and run in, while hot, with a composition called niello, — a compound of silver, lead, copper, sulphur, and borax, which was more easily fusible than silver, and of a black colour. The superfluous part of this niello which remained above the surface of the plate was then rubbed off with scrapers, and cleaned away with pumice-stone, leaving the engraved design on the plate with all the effect of a print. In order to preserve copies of their designs, the artists were in the habit before filling the design with the niello to take impressions of the plates with earth, over which liquid sulphur was poured, and from which, when cold, the earth was removed. But Finiguerra carried his practice beyond this; for with a mixture of soot and oil he filled the cavities of the engraving, and by pressing damp paper upon it with a roller, obtained impressions on the paper, having, as Vasari says, all the appearance of drawings done with a pen, "venivano come disignate di penna." Bartsch, in his *Essay on the History and Discovery of the Art of taking Impressions from Engravings*, prefixed to the thirteenth volume of his work *Le Peinteur Graveur*, very unwillingly admits the invention to have originated with Finiguerra, though he claims for the Germans the merit of applying it to practice for the multiplication of copies of pictures, &c.; but to this the opposing arguments of Mr. Ottley are so powerful that we apprehend the subject is not likely to be again mooted. Finiguerra was followed by Baccio Baldini, a goldsmith of Florence, who, according to Vasari, employed Sandro Botticelli to design for him. Mr. Ottley doubts, however, the inference that might be drawn from this passage; and indeed it does not appear likely that such an artist as Botticelli could have resigned himself to employment in such works as Baldini would be constantly requiring. Baccio's works were numerous, and are of course much sought after by collectors. Botticelli, a painter of eminence as well as an engraver, was a native of Florence, where he was born in 1437. He is spoken of with praise by Vasari, and especially for his picture at San Pietro Maggiore, of the Assumption of the Virgin: among the works he engraved from his own designs are subjects illustrative of Dante, and a number of prints of prophets and sybils. His death occurred in 1515. Contemporary with him flourished Antonio del Pollajuolo, and rather later Gherardo and Robetta, who advanced the art; though it was still dry in execution, and more to be admired for correctness of drawing and design than for any attempt at relief or effect. There can be no doubt that at this period the art was practised at Rome, though the Venetian state and other parts of the north of Italy furnished a more abundant supply of artists; — of whom Francesco Squarcione, Andrea Mantegna, Girolamo Mocetto, Marcello Fogelino, Montagna, Bramante the architect, Altobello, Gio. Bat. del Porto, Giovanni Maria, and Giovanni and Antonio de Brescia were among the most eminent. The works of Mantegna exhibit great marks of improvement on the Florentine school, and are characterized by a vigour and facility of execution which might naturally be expected, considering the rapid strides towards perfection made in the other arts.

In Germany and the Low Countries the art of engraving had made extraordinary progress during the fifteenth century; and the name of Martin Schoen or Schongauer must not be forgotten. This artist, who was also a painter and goldsmith, was the father of the German school of engraving. He was a native of Culmbach in Franconia, and born about 1420. He began the practice of the art when it was in its infancy, and succeeded in carrying it to a great degree of perfection. His death occurred at Colmar in 1486. Vasari relates that Michael Angelo, when young, was so pleased with a print by Schongauer, representing St. Anthony tormented by devils, that he copied it in colours. Albert Durer, the most celebrated of the early engravers of Germany, was born at Nuremburg, in 1471. Skilled in many arts, and a painter of no ordinary powers, it is astonishing that, in a life not exceeding fifty-eight years, he should have succeeded so eminently in that of engraving that he has even hardly been surpassed. On copper as well as wood his works exhibit specimens of executive excellence, which the experience of centuries has not been able to surpass. Durer is supposed to have been the inventor of the art of etching, at least no etchings are known before those which are extant from his hand. Of the works he has left, which are very numerous, his wood engravings are the most free and masterly. Following Albert Durer were Aldegrever his pupil, Hans Beham and his brother Bartholomew, Altdorfer, Binck, Goerting, Penz, and Solis. Hans Holbein, who, according to some was a native of Basle, and according to others of Augsburg, besides acquiring celebrity as a painter is known as an engraver on wood, executed many pieces; the best known and most remarkable of which are the fifty-three prints called the "Dance of Death," first published about 1530. Of the Dutch and Flemish schools Lucas van Leyden must be considered the head. Born in 1494, at the place whence he derives his name, he was the contemporary and friend of Albert Durer; to whom, though inferior in design, he was superior in composition. His works, which were both on wood and copper, are few in number. The Low Countries furnished a host of engravers, among whom we think it unnecessary to name more than the Sadelers; Bloemart, who laid the foundation of the principles upon which lines become capable of expressing quality, colour, and chiaroscuro, which the French engravers afterwards improved; Goltzius and his pupils; Muller; and Lucas Kiliau: the three last, though they handled the graver with great freedom and dexterity, fell into boundless absurdity and extravagance, which, however, were tempered and corrected by Mathieu and Saenredam. In the beginning of the seventeenth century the two Bolswerts appeared, whose style was much improved by the instructions of Rubens. Vosterman, Pontius, and Peter de Jode the younger were of this school, which is distinguished for the success and correctness with which it transferred the picture to the copper. Rembrandt, notwithstanding all his faults and absurdities, claims a special notice in this place as an engraver. The Descent from the Cross, and the print called the "Hundred Guilder Print," are extraordinary efforts of art. His portraits and landscapes are full of nature, expression, and character; and it is difficult to say whether he is more successful in his sunshine effects, than in the sober solemn twilight with which his varied subjects are enveloped. Vandyke has left a few specimens of etchings worthy of his name. Jegher, Lutma, and above all the family of the Vischers, exhibited great excellence in the art, which continued to advance under the hands of Waterloo, Jacob Ruysdael, and Paul Potter; the last of whom, in his etchings of animals, displayed a scientific acquaintance with drawing and anatomy till his time unpractised.

We must now return to close the brief account of the Italian school, in which the appearance of Marc Antonio Raimondi forms the most splendid era. Born at Bologna about 1488, he became the pupil of Raibolini, an artist of that city. His master in the art of engraving is, however, unknown. We first hear of him at Venice, whither Albert Durer went to institute proceedings against him for pirating his prints, which had been copied by Raimondi with such wonderful accuracy that they were sold for the originals. But the proper sphere for Marc

Antonio was Rome, whither he soon bent his steps. There his merit soon gained him the friendship and esteem of Raffaelle, then in the plenitude of his glory, by whom he was employed to engrave from his designs. His first plate from a design by Raffaelle was the Lucretia, soon after which he executed the Judgment of Paris. His engravings after this master are very numerous; and though free from the blandishments of style, chiaroscuro, and local colour which the art has received since his time, such was his knowledge of drawing, such the beautiful character that pervades his works, that he is entitled to the highest rank in the art to which excellence has ever attained. Strutt considers him one of the most extraordinary engravers that ever lived. His school attracted to Rome artists from all parts; among whom may be enumerated Marco de Ravenna, Giulio Bonasoni, Agostino de Musis, Enea Vico, and Nicolo Beatrici. Some of the German artists whom we have named above — viz. Beham, Penz and James Binck — resorted to Rome for the benefit of his instructions. On the death of Raffaelle, he executed engravings of some of the works of Giulio Romano. His last print, the Battle of the Lapithæ, is dated 1539. Some of the principal pupils of Marc Antonio have already been named; to them may be added Georgio Grisi, commonly called Mantuanus, and others of his family. Many of the Italian painters were extremely successful in engraving, among whom Titian etched many landscapes; but none cultivated the art with more success than Agostino Caracci, who studied under Cornelius Cort, a Dutch engraver, born at Hoorn in 1536. His design and execution are equally to be admired; and had he but concentrated his lights more, and attended to local colour, he would have been exceeded by none. In the seventeenth century Della Bella, Callot (who, though born in France, belongs to the Italian school), Guercino, Salvator Rosa, and Claude continued the reputation of the art. At the latter end of this century was born Antonio Canaletti, originally a scene painter, like his father Bernardo. His etchings opened an entirely new field in architectural engraving, and may be considered almost if not quite the first in which fine sparkling effects of light are introduced, and in which the darkest shadows partake of the transparency and clearness which nature herself exhibits. Piranesi, who was born in Venice, and died in 1770, appeared about the middle of that century: he was one of the most surprising architectural engravers that have ever existed, whether we consider the astonishing power or number of his works. His use of the etching needle surpassed all that has been done before or since; and in our own time Volpato of Florence, who, besides his other works, engraved almost all the celebrated performances of Canova with a delicacy, grace, and correctness of the first order.

The French school commenced about the middle of the sixteenth century with Noel Garnier, who was followed by many clever artists; but till the time of Louis XIV. it cannot be said to have been highly distinguished. At that epoch we have Gerard Edelinck, who, though born at Antwerp, belongs properly to the French school, and Gerard Audran. The former of these, who worked entirely with the graver, carried what is called colour in engraving to a much greater degree of perfection than had ever before been practised. His facility was amazing, and portrait and history were equally the subjects of his burin. The name of Audran, not less from the circumstance of the family having produced six engravers, than for Gerard Audran, who engraved the well-known Battles of Alexander after Le Brun, is conspicuous in the history of the art; his name, however, will descend to posterity with greater lustre from his engravings after the Italian school, and particularly those of Nicolo Poussin. Gerard Audran was born at Lyons in 1640, and died in Paris in 1703. John Audran, the last of the family who exercised the art, and nephew of Girard, died in 1756. Nanteuil, the three Drevets, of whom Peter was the most eminent, Le Clerc, Chereau, Cochin, Beauvais, Simonneau Dupuis, and many other masters belong to this period; but Balechon and Wille, towards the middle of the century, outstripped all that had been done by their predecessors. Wille was a German; but his residence having been chiefly at Paris, he is always ranked among the French engravers. His extraordinary powers in imitating the qualities of objects, and particularly of satin, the smoothness of effect he produced, and his extraordinary clearness in the use of the graver, entitle him to a place of the first rank in the French school, which, since the age of Louis XIV., has been more distinguished for its great mechanical skill, than for grace, correctness, and beauty in the higher departments of the art.

Till the middle of the seventeenth century England was indebted to foreign artists for the embellishment bestowed upon the typographical works she produced, as well as for such engravings, either in history, portrait, or landscape, as the taste of the nation required. Among the artists who visited England and made it their permanent or temporary residence were the Passes, Vaillant, Hondius, Vosterman, Hollar, Blooteling, Dorigny, and several others. Payne, who died about 1648, and Faithorne, who executed many historical pieces and portraits in a masterly manner, were the earliest English engravers deserving mention. William Faithorne, son of the last named, was eminent as one of the earliest mezzotinto engravers; a species of engraving of English invention, if the editor of *Wren's Pacentalia* can be relied on, and discovered, according to him, by his eminent relation, Sir Christopher Wren. This invention, which is usually attributed to Prince Rupert, is claimed by Heineken for Lieutenant-Colonel Siegen, who was a Hessian officer, from whom Heineken says Prince Rupert learned the secret, which he brought to England on his return with Charles II. After the two Whites, father and son, appeared Vertue, who was born in 1684. He was the scholar of Vandergucht, and from the numerous works he brought out must have been an artist of great industry and facility. The larger portion of his labours was confined to portraits. Vertue died in 1757, and left behind him a History of Painting and Painters in England, which was published by Horace Walpole in 4 quarto volumes. The works of Pond and Knapton can only be mentioned as continuing the history, though occasionally they possess some spirit; but Vivares, a Frenchman by birth, belonging, however, to the English school, and indeed the founder of it in landscape engraving, has shown in his engravings from the pictures of Claude talents, the precursors of that pre-eminence in landscape engraving which this country has not only improved upon but exclusively possessed. Woollett carried execution to a far greater extent than Vivares, uniting with that engraver's spirit all the elegance, clearness, and delicacy of the French school; and to these Woollett superadded every beauty that mechanical skill could effect. John Browne was a contemporary worthy of Woollett, whose works after Salvator, Both, and others are well executed. Sir Robert Strange distinguished himself by his great mechanical skill, whence resulted beautiful execution, by the breadth he preserved in the effects he copied, and by the delicacy he imparted to flesh in a manner that has never been equalled. His principal engravings are from the Italian painters, especially Titian, Guido, and Corregio, and reflect great honour on the English school, which since his time has never been deficient in producing artists of the first class. Strange was a native of one of the Orkney Islands, where he was born in 1721, and died in 1792. Since his time the names of artists of talent might be here supplied to a very great extent: we shall merely mention those of Basire, Bartolozzi, Rooker, Heath, Byrne, Bromley, Lowry, Earlom, Raphael, Smith, &c. In the present day the demand of prints for the embellishment of books has produced talent which perhaps might be more nobly employed in works of a higher order. In the enumeration of masters it will be seen that the name of Hogarth does not find a place, — for which our reason is that his engravings partake more of the nature of pictures transferred at once to copper, often without proceeding through the intermediate stage.

Engraving on Wood, or Xylography.—In this branch of the art the material used is a block of box or pear-tree wood, cut at right angles to the direction of the fibres, its thickness being regulated by the size of the print to be executed. The subject is drawn on the block with a black-lead pencil, or with a pen and Indian ink, taking care that the whole effect is represented in the lines so drawn. The whole of the wood is then cut away, except where the lines are drawn, which are left as raised parts; in which point it is that this mode of engraving differs so essentially from copper-plate engraving, wherein the lines are cut out or sunk in the metal, instead of being raised from it. The impressions from wood blocks are taken in the same manner as from printing types.

Engraving on Copper is performed by cutting lines representing the subject on a copper-plate by means of a steel instrument ending in an unequal-sided pyramidal point, such instrument being called a graver or burin, without the use of aquafortis; which mode will be seen below, under the art. ETCHING. Besides the graver there are other instruments used in the process; viz. a scraper, a burnisher, an oil stone, and a cushion for supporting the plate. In cutting the lines on the copper the graver is pushed forward in the direction required, being held in the hand at a small inclination to the plane of the copper. The use of the burnisher is to soften down lines that are cut too deep, and for burnishing out scratches in the copper: it is about three inches long. The scraper, like the last, is of steel, with three sharp edges to it, and about six inches long, tapering towards the end. Its use is to scrape off the burr raised by the action of the graver. To show the appearance of the work during its progress, and to polish off the burr, engravers use a roll of woollen or felt called a rubber, which is put in action with a little olive oil. The cushion, which is a leather bag about nine inches diameter filled with sand for laying the plate on, is now rarely used except by writing engravers. For architectural subjects, or in skies, where a series of parallel

lines are wanted, an ingenious machine was invented by the late Mr. Wilson Lowry, called a ruling machine, the accuracy of whose operation is exceedingly perfect. This is made to act on an etching ground by a point or knife connected with the apparatus, and bit in with aquafortis in the ordinary way.

Etching is a species of engraving on copper or other metals with a sharp-pointed instrument called an etching needle. The plate is covered with a ground or varnish capable of resisting the action of aquafortis. The usual method is to draw the design on paper with a black-lead pencil; the paper being damped and laid upon the plate, prepared as above, with the drawing next the etching ground, is passed through the rolling press, and thus the design is transferred from the paper to the ground. The needle then scratches out the lines of the design; and aquafortis being poured over the plate, which is bordered round with wax, it is allowed to remain on it long enough to corrode or bite in the lines which the etching needle has made. Etching with a dry point, as it is called, is performed entirely with the point without any ground, the burr raised being taken off by the scraper. Etching with a soft ground is used to imitate chalk or black-lead drawings. For this purpose the ground is mixed with a portion of tallow or lard, according to the temperature of the air. A piece of thin paper being attached to the plate at the four corners by some turner's pitch and lying over the ground, the drawing is made on the paper and shadowed with the black-lead pencil. The action of the pencil thus detaches the ground which adheres to the paper, according to the degree to which the finishing is carried: the paper being then removed, the work is bit in in the ordinary way. *Stippling* is also executed on the etching ground by dots instead of lines made with the etching needle, which, according to the intensity of the shadow to be represented, are made thicker and closer. The work is then bit in. *Etching on Steel* is executed much in the same way as in the process on copper. The plate is bedded on common glazier's putty, and a ground of Brunswick black is laid in the usual way, through which the needle scratches. It is then bit in, in the way above described.

Mezzotinto Engraving.— In this species of engraving the artist, with a knife or instrument made for the purpose, roughs over the whole surface of the copper in every direction, so as to make it susceptible of delivering a uniform black, smooth, or flat tint. After this process the outline is traced with an etching needle, and the lightest parts are scraped out, then the middle tints so as to leave a greater portion of the ground, and so on according to the depth required in the several parts of the work.

Aquatinta Engraving, whose effect somewhat resembles that of an Indian-ink drawing. The mode of effecting this is (the design being already etched) to cover the plate with a ground made of resin and Burgundy pitch or mastic dissolved in rectified spirit of wine, which is poured over the plate lying in an inclined position. The spirit of wine, from its rapid evaporation, leaves the rest of the composition with a granulated texture over the whole of the plate, by which means a grain is produced by the aquafortis on the parts left open by the evaporation of the spirit of wine. The margin of the plate is of course protected in the usual way. After the aquafortis has bitten the lighter parts they are *stopt out*, and the aquafortis is again applied, and so on as often as any parts continue to require more depth. Formerly the grain used to be produced by covering the copper with a powder or some substance which took a granulated form, instead of using the compound above mentioned; but this process was found to be both uncertain and imperfect. In the compound the grain is rendered finer or coarser, in proportion to the quantity of resin introduced. This mode of engraving was invented by a Frenchman of the name of St. Non, about 1662. He communicated it to Jean Baptiste le Prince; who died in 1781, from whom it was acquired by Paul Sandby, who introduced it through the medium of Mr. Jukes into England. It has been practised in this country with much greater success than elsewhere.

Etching on Glass.— The glass is covered with a thin ground of beeswax: and the design being drawn with the etching needle, it is subjected to the action of sulphuric acid sprinkled over with pounded fluor or Derbyshire spar. After four or five hours this is removed, and the glass cleaned off with oil of turpentine, leaving the parts covered with the beeswax untouched. This operation may be inverted by drawing the design on the glass with a solution of beeswax and turpentine, and subjecting the ground to the action of the acid.

Engraving on Stone, or *Lithography* (λιθος, *a stone*, and γραφειν, *to write or draw*). A modern invention, by means whereof impressions may be taken from drawings made on stone. The merit of this discovery belongs to Aloys Senefelder, a musical performer of the theatre at Munich about the year 1800. The following are the principles on which the art of lithography depends: — First, the facility with which calcareous stones imbibe water; second, the great disposition they have to adhere to resinous and oily substances; third, the affinity between each other of oily and resinous substances, and the power they possess of repelling water or a body moistened with water. Hence, when drawings are made on a polished surface of calcareous stone with a resinous or oily medium, they are so adhesive that nothing short of mechanical means can effect their separation from it, and whilst the other parts of the stone take up the water poured upon them, the resinous or oily parts repel it. Lastly, when over a stone prepared in this manner a coloured oily or resinous substance is passed, it will adhere to the drawings made as above, and not to the watery parts of the stone. It was formerly thought that this country did not possess a sort of stone like that of Germany suitable to the purposes of lithography; this, however, is now known to be erroneous, as the neighbourhood of Bath abounds with it, being the white *lias*, which lies immediately under the blue. It is also found in Scotland. The ink and chalk used in lithography are of a saponaceous quality: the former is prepared in Germany from a compound of tallow soap, pure white wax, a small quantity of tallow, and a portion of lamp-black, all boiled together, and when cool dissolved in distilled water. The chalk for the crayons used in drawing on the stone is a composition consisting of the ingredients above mentioned, but to it is added when boiling a small quantity of potash. After the drawing on the stone has been executed and is perfectly dry, a very weak solution of vitriolic acid is poured upon the stone, which not only takes up the alkali from the chalk or ink, as the case may be, leaving an insoluble substance behind it, but it lowers in a very small degree that part of the surface of the stone not drawn upon, and prepares it for absorbing water with greater freedom. Weak gum water is then applied to the stone, to close its pores and keep it moist. The stone is now washed with water, and the daubing ink applied with balls as in printing; after which it is passed in the usual way through the press, the process of watering and daubing being applied for every impression.

There is a mode of transferring drawings made with the chemical ink on paper prepared with a solution of size or gum tragacanth, which being *laid on the stone and passed through the press* leaves the drawing on the stone, and the process above described for preparing the stone and taking the impressions is carried into effect.

In Germany many engravings are made on stone with the burin, in the same way as on copper; but the very great inferiority of these to copper engravings makes it improbable that this method will ever come into general use.

Perhaps one of the greatest advantages of the art of lithography is the extraordinary number of copies that may be taken from a block. As many as 70,000 copies or prints have been taken from one block, and the last of them nearly as good as the first. Expedition is also gained, inasmuch as a fifth more copies can be taken in the same time than from a copper-plate: and as regards economy the advantage over every other species of engraving is very great.

Zincography.— This art, which is of very recent introduction in this country (so much so, indeed, that but few specimens are as yet to be seen), is similar in principle to lithography, the surface of the plates of zinc on which it is executed being bit away, leaving the design prominent or in relief. We have seen some beautiful examples of this art, but varying little in their appearance from those of stone engraving.

ENGRO'SSING. The writing of a deed over fair, and in proper legible characters. Among lawyers it more particularly means the copying of any writing upon parchment or stamped paper. In statute law, engrossing means the buying up of large quantities of any commodity in order to sell it again at an unusually high price. *See* FORESTALLING.

ENHARMO'NIC SCALE. In Music, a scale in which the modulation proceeds by intervals less than semitones; that is, by quarter tones, having two dieses or signs of raising or lowering the voice.

ENI'GMA. (Gr. αινιγμα.) A proposition put in obscure or ambiguous terms to puzzle or exercise the ingenuity in discovering its meaning. In the present day, the enigma is only a jeu d'esprit, or a species of amusement to beguile a leisure hour; but formerly it was a matter of such importance that the eastern monarchs used to send mutual embassies for the solution of enigmas. Every one remembers the enigma which Sampson proposed to the Philistines for solution; and the still more famous enigma of the Sphinx (quod vide), the source at once of the elevation and the misfortunes of Œdipus. About the 17th century the enigma, which had been for centuries neglected as a species of literary display, again came into favour; and in France particularly it was cultivated with so much zeal, that several grand treatises were dedicated to its history and characteristics. The best enigmas with which we are acquainted were written by Schiller, and have been incorporated in his works. Even in the present day the periodical literature of France and Germany does not disdain this species of writing; though, as was before observed, it is now employed gene-

rally for amusement, and rarely to convey moral instruction.

ENLI'STMENT, in Military and Naval affairs, means a voluntary engagement to serve as a private soldier or sailor, either for a fixed or unlimited period. Unlike the armies of the Continental nations, whose ranks are generally supplied by conscription, the troops of the British army in all its departments, whether of the line, artillery, or East India Company, are obtained by voluntary enlistment. About a century ago, it was usual to engage recruits for the period of three years; but the present practice is to enlist either for an unlimited period, as during the continuance of a war, or for certain defined numbers of years, which vary in the different classes of troops. For the infantry the period is seven years; for the cavalry ten years; for the artillery twelve years; and for the East India Company for an unlimited time or twelve years, provided the recruit be upwards of eighteen years of age, otherwise the difference between his age and eighteen years is added to each period. (*Penny Cyclo.*) By an act passed in 1819, called the Foreign Enlistment Act, no British subject was allowed to enter foreign service without permission from the crown; and though this act was recently suspended for three successive years in favour of the troops raised in this country for the service of the Queen of Spain, it is once more in full operation.

The navy of Great Britain is also manned by voluntary enlistment; though in time of war, or on other great emergencies, impressment (quod vide) is often resorted to for obtaining adequate supplies. The period of engaging to serve in the navy was, by an act passed in 1835, limited to five years; after which the sailor is entitled, under certain beneficial restrictions, to his discharge, with the privilege, however, of re-enlisting for a similar period.

E'NNEAGON. (Gr. ἐννεα, *nine*; γωνια, *angle*.) A plane geometrical figure bounded by nine sides. When the figure is regular and the side supposed $=1$, the area is 6·18182.

ENNEA'NDROUS. In Botany, having nine stamens.

ENNUI', a French term wholly naturalized in England, signifies a kind of listlessness or inaptitude for mental exertion; or it may be more scientifically defined as that uneasiness or languor which prevails during the absence of mental impressions. The Italian word *noja* corresponds to the French *ennui*.

ENRO'LMENT (in legal orthography, more properly, Inrolment), signifies in law the registering or entering of any document or lawful act in the rolls of the chancery, or superior courts of common law, or in the records of the quarter sessions. Such inrolment is rendered necessary in different cases by statute; as a deed of bargain and sale in order to pass lands must be inrolled in one of the courts of record at Westminster, or by the clerk of the peace in any county, by 27 H. 8. c. 16. Every deed before it is inrolled is to be acknowledged to be the deed of the party before a master in chancery, or a judge of the court in which it is inrolled.

ENSE'MBLE. (Fr.) In the Fine Arts, a term denoting the masses and details considered with relation to each other.

E'NSIGN. The national flag carried by a ship. Men of war carry a red, a white, or a blue ensign, according to the colour of the flag of the admiral in command of the station. Ships do not display their ensigns at sea, except in meeting strangers, on which ships show their national ensign. In harbour the ensign is not shown before 8 A.M., nor after sunset.

The ensign hoisted with the upper corner (or in British ships the *union* of the crosses of St. George and St. Andrew) downwards, is the signal of distress.

The English ensign is a red, white, or blue flag, having the union in the upper corner next the mast.

E'NSIGN. The lowest commissioned officer, subordinate to the lieutenants, in a regiment of infantry. An ensign is appointed to each company, and the junior ensigns carry the colours of the regiment. In the artillery and in the rifle brigade a second lieutenant takes the place of an ensign.

ENTA'BLATURE. (Fr. entablement.) In Architecture, the whole of the parts of an order above the column. The assemblage is divided into three parts: the architrave, which rests immediately on the column; the frieze next, over the architrave, being the middle member; and the cornice, which is the uppermost part. The first and last are variously subdivided in the different orders. *See* ORDER.

ENTAI'L. *See* FEE TAIL.

E'NTASIS. (Gr. ἐντασις.) In Architecture, a delicate and almost imperceptible swelling of the shaft of a column, to be found in almost all the Grecian examples, adopted to prevent the shafts being strictly frusta of cones. This refinement, which is alluded to in the second chapter of the third book of *Vitruvius*, was first observed in execution by Mr. Allason in 1814 in the Athenian edifices.

ENTE'LECHY. (Gr. ἐντελέχεια; from ἐντελὴς, *perfect*, and ἔχω, *I hold*.) A peripatetic term, invented by Aristotle in order to express an object in its complete actualization, as opposed to merely *potential* existence (τὸ δυνάμει ὂν). *See* ARISTOTELIAN PHILOSOPHY.

ENTELMI'NTHA. (Gr. ἐντος, *within*, and ἕλμινς, *a worm*.) A name synonymous with *Entozoa*, and applied to the same heterogeneous group of invertebrate animals. *See* CŒLELMINTHA and STERELMINTHA.

ENTERI'TIS. (Gr. ἐντερα, *the intestines*.) Inflammation of the bowels. This disease is frequently occasioned by incautious exposure to cold, by acrid substances or hardened fæces in the bowels. Its symptoms are, pain over the abdomen; thirst, heat, and excessive restlessness and anxiety; sickness; obstinate constipation; and a hard, small, and quick pulse. The pain increases as the disease proceeds, especially about the navel; there is great difficulty in voiding the urine, which is small in quantity and high-coloured; and the abdomen is so tender as not to endure the slightest pressure. It often terminates in a few hours in mortification of a part of the intestinal canal; in which case the pain suddenly ceases, the belly becomes tumid, the pulse sinks rapidly, and the countenance acquires a peculiar ghastliness: it also proves fatal during the inflammatory stage. Favourable symptoms are, a gradual diminution of pain and of tenderness on pressure, natural evacuation by the bowels, moist skin, equal and firm pulse, and a copious discharge of urine depositing abundance of red sediment. This is a disease which requires prompt and decided treatment, more especially as relates to bleeding, which should be carried as far as the strength will allow upon the first accession of the inflammation. Leeches should be applied over the abdomen, and the patient should be put in a hot bath, or fomented with hot water: the lower bowels should be evacuated by a glyster of castor oil and gruel; and small doses of saline purgatives, or of calomel and cathartic extract, should be administered to clear the bowels. The stomach, however, is very apt to reject these remedies, and sickness should be avoided: it must be quelled by the effervescing draught, with a very few drops of tincture of opium. In some cases pretty large doses of calomel and opium have been given with success. When the urgent symptoms give way, and the bowels have been cleared, diaphoretic saline medicines and gentle aperients may be used, and a mild nourishing diet allowed; but great care is requisite in ascertaining that all relics of the inflammatory action are got rid of, and that it is not lurking in some one spot in a chronic form.

E'NTEROCE'LE. (Gr. ἐντερα, *the bowels*, and κηλη, *tumour*.) A hernia or rupture, the contents of which are a portion of intestine.

ENTERODE'LA. (Gr. ἐντερα, and δηλος, *manifest*.) The name given by Ehrenberg to a section of his class *Polygastrica*, comprehending those which have a complete alimentary canal terminated by a mouth and anus.

E'NTEROEPI'PLOCE'LE. (Gr. ἐντερα; ἐπιπλοον, *the omentum*; κηλη, *tumour*.) A hernia or rupture containing both intestine and omentum.

ENTERO'LOGY. (Gr.) A treatise on the bowels.

ENTHYME'ME (Gr. ἐν, and θυμος, *mind*; something understood in the mind and not expressed), in Logic, is commonly defined to be an argument having one premiss expressed, the other understood. (*See* LOGIC, SYLLOGISM.) This is the character under which the universal form of reasoning, or syllogism, generally presents itself in connected writing. For example, the following argument, if drawn out in the correct logical form, would stand thus, "All tyrants deserve death; but Cæsar is a tyrant, therefore Cæsar deserves death." But in the rapid diction of oratory, or poetry, it would probably be expressed either, "All tyrants deserve death, therefore so does Cæsar;" in which case the minor premiss, "Cæsar is a tyrant," is suppressed: or, "Cæsar is a tyrant, therefore he deserves death," by suppressing the major premiss. Instances may be cited in which the enthymeme consists merely of one of the premisses expressed, while both the other premiss and the conclusion are to be supplied by a rapid exercise of thought. Thus in the well-known words, "But Brutus says he was ambitious, and Brutus is an honourable man," the last of these propositions contains a complete argument, — "what honourable men say is to be believed: Brutus is an honourable man, therefore what Brutus says is to be believed."

ENTOMO'LOGY. (Gr. ἐντομα, *insects*, and λογος, *a discourse*.) The science of insects: the history of the organization, habits, properties, and classification of those articulated animals which are distinguished by the presence of antennæ and of breathing organs, composed of ramified tracheæ with or without air-sacs. The name insect, from its etymological signification of an animal insected or divided into sections, is applicable to the greater part of the Articulate sub-kingdom, but is now restricted to those species characterized as above. The presence of highly developed organs for breathing air, together with peculiar and complex organs of sensation, is associated, as might be expected, with active powers of locomotion; and most insects, besides having articulated

members for terrestrial progression, for leaping or climbing, swimming or diving, are endowed with wings, and are capable of rapid and extensive flight. The power of traversing space is given in greater fulness and perfection to the class of insects than to any other created beings on our planet. A peculiar condition of the breathing organs, and a peculiar animal tissue (chitine), which combines great strength, elasticity, and levity, coexist in insects, and in insects only. If, therefore, the highest of living created animals contain the characteristic structures of all lower forms, as some transcendental anatomists assume, then man is not the acmé or apotheosis of animal organization; for neither anastomosing tracheæ nor a particle of chitine is present in his system; nor does he possess a thousandth part of the locomotive energies of certain insects.

Those insects which have more than six articulated legs, and have the segments of the trunk free, without distinction of thorax and abdomen, which undergo no other metamorphosis than acquiring an increased number of segments after exclusion from the egg, and which lastly possess neither compound eyes nor wings, are separated by some zoologists as a distinct class, under the name *Myriapoda*, which see.

In the Hexapod insects, the body is divided into a head, thorax, and abdomen; the head supports a pair of antennæ, and contains a pair of compound, and often also simple eyes; the mouth is provided with a labium, labrum, mandibulæ, and maxillæ; the labium and maxillæ also support peculiar feeling organs, called palpi. Sometimes these parts of the mouth, which are termed collectively trophi, or oral organs, are distinct, and adapted to mastication: the insects thus characterized constitute an extensive primary division of the class termed *Mandibulata*. Those insects in which the trophi are so modified as to form an instrument of suction are included in the primary division called *Haustellata*.

The Hexapod insects were divided by Linnæus into the following orders:—

1. *Coleoptera*. Wings four, the upper pair hard, with a straight suture. Ex.: Beetles and earwigs.
2. *Hemiptera*. Wings four, the upper pair moderately hard and incumbent. Ex.: Bugs, locusts, tree-hoppers, plant-lice, &c.
3. *Lepidoptera*. Wings four, covered with scales. Ex.: Moths and butterflies.
4. *Neuroptera*. Wings four, membranaceous; anus unarmed. Ex.: Dragon-flies, May-flies, &c.
5. *Hymenoptera*. Wings four, membranaceous; anus aculeate. Ex.: Bees, ants, saw-flies, &c.
6. *Diptera*. Wings two; halteres two, in place of the posterior wings. Ex.: Flies.
7. *Aptera*. Wings none. In this order Linnæus included not only true Apterous insects, as fleas, but also centipedes, spiders, crabs, lobsters, &c.; or the articulate animals now forming the classes *Myriapoda*, *Arachnida*, and *Crustacea*.

There is not, perhaps, any class of the animal kingdom which has been the subject of more numerous and various attempts at classification than that of insects. We have just seen that Linnæus adopted the locomotive system as the basis of his method. Fabricius, his pupil, proposed a system founded on modifications of the structure of the mouth. Latreille endeavoured to form a natural classification of those most numerous animals from a consideration of their entire organization. His latest system is as follows:—

Sub-class I. *Aptera*. No wings; simple eyes in most.

A. No metamorphosis, but simple moulting, without a season of torpidity; mouth in some a simple sucker, in others mandibulate.

Order 1. *Thysanura*.

2. *Anoploura* (or *Parasita*).

B. A complete metamorphosis, larvæ apodal; pupæ torpid; mouth haustellate, composed of an articulate sheath containing three setæ, with two scales at their base; body much compressed; the species saltatory and parasitic.

3. *Aphaniptera* (or *Siphonaptera*).

Sub-class II. *Ptilota*. Wings, but sometimes not developed as such; two compound eyes, to which in many are added simple eyes.

A. Two wings covered by two elytra, either crustaceous or coriaceous.

a. Mandibles and maxillæ; elytra of the same consistence.

4. *Coleoptera*.
5. *Dermaptera*.
6. *Orthoptera*.

b. No mandibles nor maxillæ; mouth haustellate, composed of an articulate sheath, including four setæ; elytra membranous at their extremity in most.

7. *Hemiptera*.

B. Wings four, or two; not covered by elytra.

a. Mandibulate; wings four, membranous, and generally transparent; a small scale (tegulum) at the base of the two anterior wings.

8. *Neuroptera*.
9. *Hymenoptera*.

b. Haustellate; wings scaly; tegula large, and thrown back.

10. *Lepidoptera*.

c. Two wings; haustellate.

11. *Strepsiptera* (or *Rhipiptera*).
12. *Diptera*.

For the characters of the above orders see the articles under their respective denominations.

ENTOMO'PHAGA. (Gr. ἐντομα, *insects*, and φαγω, *I eat*.) A tribe of Marsupial quadrupeds, characterized by having three kinds of teeth — viz. incisors, canines, and molares — in both jaws, and the intestinal canal provided with a moderate-sized cœcum. The Opossums (*Didelphys*), Bandicoots (*Perameles*), and the genera *Myrmecobius* and *Chæropus* are associated to form this group; and feed principally, though not exclusively, on insects.

E'NTOMO'STRACANS. (Gr. ἐντομος, *incised*, and ὀστρακον, *a shell*.) A division of the class *Crustacea*, including those species which are covered with a thin horny tegument in the form of a shell, and consisting of one or two pieces.

ENTOZO'A. (Gr. ἐντος, and ζωον, *an animal*.) A name given to an extensive series of low-organized invertebrate and generally vermiform animals, of which the greater part are parasitic on the internal organs of other animals. They have colourless blood, circulated in the higher organized species in a closed system of vessels, without an auricle or ventricle; they have no respiratory organs, no articulated members for locomotion, no organs of sense. The digestive system consists either of tubes or cavities excavated in the parenchymatous texture of the body, and without an anal outlet; or of a tube with both oral and anal orifices freely suspended in an abdominal cavity. A filamentary nervous system has been recognized in the higher organized Entozoa, occasionally complicated with a ganglion near the mouth; the generative system is unisexual, hermaphrodite, or diœcious. (For the classification of the Entozoa, see INTESTINALIA.) The species of Entozoa known to infest the human body are the following:—*Ascaris vermicularis*, *Ascaris lumbricoides*, *Tricocephalus dispar*, *Bothriocephalus latus*, *Tœnia solium*, in the alimentary canal; *Distoma hepaticum*, in the gall-bladder; *Acephalocystis endogena*, *Echinococcus hominis*, in the substance of the liver, in the omentum and cavity of the abdomen; *Filaria bronchialis*, in the bronchial glands; *Strongylus gigas*, in the kidney; *Spiroptera hominis* and *Strongylus spiniger*, in the urinary bladder; *Polystoma pinguicola*, in the ovarium; *Trichina spiralis*, in the voluntary muscles; *Cysticercus cellulosæ*, *Filaria medinensis*, and *Filaria oculi*, in the cellular tissue.

ENTREPOT. In Commerce, the name given in France and some other countries to a warehouse or other place where goods brought from abroad may be deposited, and from whence they may be withdrawn for export to another country, without payment of any tax or duty. An entrepôt is, therefore, synonymous with what is called a free port on the Continent, and in this country with a *bonded warehouse;* that is, a warehouse in which foreign products are stored under the joint locks of the king and the importer: if such products be entered for home consumption, they are free of duty till their entry; and if they be re-exported to a foreign country, they are exempted from all duty, and merely pay a small sum as warehouse rent. In popular language, however, the word entrepôt is frequently employed to designate a sea-port or commercial town which exports the produce of a considerable adjacent territory, and imports the foreign articles required for its supply. But its correct signification is that given above.

E'NTRESOL. (Fr.) In Architecture. *See* MEZZANINE.

ENTRO'PIUM. (Gr. ἐν, *in*, and τρεπειν, *to turn*.) A turning in of the eyelashes and eyelid, so as to irritate the ball of the eye.

E'NTRY, in Law, signifies the taking possession of lands and tenements where a man has title of entry. It is also used for a writ of possession. Entry is either actual, made by the party or his attorney; or an entry in law, by continual claim. Remedy by entry takes place in cases of abatement, intrusion, and disseisin; not on discontinuance or deforcement.

E'NVELOPE. In Fortification, a mound of earth, raised to cover some weak part of the works. Envelopes are sometimes raised in the ditch of the place, sometimes beyond it; and are in the form of a single parapet, or a small parapet bordered by another.

E'NVOYS, ORDINARY and EXTRAORDINARY, belong to the second order of diplomatic ministers. They are inferior in rank to ambassadors, properly so called; the chief difference between them being that the latter are held to represent the interests of their sovereign as agents, the former his person. *See* AMBASSADOR.

E'OCE'NE. (Gr. ἠως, *the morning*, and καινος, *recent*.) In Geology. "This period we shall call *Eocene*, because

the extremely small proportion of living species contained in these strata indicates what may be considered the first commencement or *dawn* of the existing state of the animal creation. To this period the formations first called tertiary, of the Paris and London basins, are referable." (*Lyell, Geology*.)

E'OLIPILE. *See* ÆOLIPILE.

EPA'CRIDA'CEÆ. (Epacris, one of the genera.) A natural order of shrubby Exogens, chiefly natives of Australia; they differ from *Ericeæ* chiefly in the structure of the anther, which is one-celled and destitute of appendages. The fruit of *Lissanthe sapida*, and a few other species, is eaten under the name of the Australian cranberry; otherwise there is no plant of any known use in the order, which, however, contains many beautiful species of the genera *Epacris*, *Lysinema*, *Sphenotoma*, *Styphelia*, and *Dracophyllum*.

E'PACT (Gr. ἐπακτος, *added or introduced*), in Chronology, denotes the moon's age at the end of the year, or the number of days by which the last new moon has preceded the beginning of the year. The common solar year consists of 365 days, and the lunar year of only 354 days: the difference is therefore 11; whence, if a new moon fall on the 1st of January in any year, the moon will be 11 days old on the 1st day of the following year, and 22 days old on the 1st of the third year. The numbers 11 and 22 are therefore the *epacts* of those years respectively. The addition of 11 to the last epact gives 33 for that of the succeeding or fourth year; but as the lunar month never exceeds 30 days, the epact cannot exceed 30; whence 30 is deducted from 33, and the epact is reduced to 3. Of the thirty days thus rejected an *embolismic* or *intercalary* month is formed, which, consequently, occurs every third year of the lunar cycle, and gives 13 lunar months to that year. In like manner the epacts of all the succeeding years of the lunar cycle are obtained; that is to say, by adding successively 11 to the epact of the former year, and rejecting 30 as often as the sum exceeds that number, the leap years being taken account of by adding one day to each lunar month which contains the 29th of February. Supposing, therefore, the epact of the first year of the cycle to be 11, the epacts of all the 19 years of which the cycle is composed will be as follows: — 11, 22, 3, 14, 25, 6, 17, 28, 9, 20, 1, 12, 23, 4, 15, 26, 7, 18, 29. But the order is interrupted at the end of the cycle; for the epact of the following year, formed in the same manner, would be 29 + 11 — 30 = 10, whereas it ought obviously to be 11, to correspond with the moon's age, all the circumstances being now supposed to be the same as they were at the commencement of the previous cycle. In order to understand this, it is necessary to remember that the lunar cycle of the ecclesiastical calendar is composed in the following manner:—The lunations are supposed to consist of 29 and 30 days alternately, or the common lunar year of 354 days; and, in order to make up 19 solar years, six embolismic or intercalary months of 30 days each are inserted in the course of the cycle, and one of 29 days at the end. Hence it follows that after adding 11 to the epact of the 19th year of the cycle, we must reject 29 instead of 30, in order to have the epact of the following year, or the first year of the following cycle.

This method of forming the epacts is adapted to the Julian calendar, and might be continued indefinitely, if the Julian intercalation were followed without interruption, and the lunar cycle, defined as above, had corresponded exactly with the lunar motions. But the intercalation is subject to correction, and the cycle is not quite exact. Hence the epacts must occasionally be adjusted; and, generally speaking, an alteration is made on the last year of each century. In the ordinary tables of the church calendar the epacts are therefore given only for a single century; but as the Gregorian calendar now in use defines precisely the length of the year, tables, though somewhat more complicated, have been formed, which show the epacts of every future year in all time to come. They may even be found by means of an algebraic formula of no great perplexity. (See the article "Calendar" in the *Encyclopedia Britannica*.) The epacts were invented by Luigi Lilio Ghiraldi, more frequently styled Aloysius Lilius, a physician of Naples, and author of the Gregorian Calendar, for the purpose of showing the days of the new moons, and thence the moon's age on any day of the year, and consequently of regulating the church festivals. It is only in ecclesiastical computations that the epacts are ever employed; in civil affairs the civilized portion of mankind have long since laid aside the use of the lunisolar year, and regulated time entirely by the sun. In the calendar of the Church of England, Easter and the other moveable feasts are determined in the same manner as in the old Romish calendar, excepting that the golden numbers are prefixed to the days of the *full moons*, instead of the days of the new moons. The epacts are consequently not used. It is desirable that the custom of reckoning time by the moon, which had its origin in ignorant ages, were abandoned, and the civil year adopted for every purpose. *See* CALENDAR.

The following table shows the epacts corresponding to each year of the lunar cycle during the present century. The year of the cycle is what is usually called the golden number, which is found by the following rule: — Add 1 to the date (or year), and divide the sum by 19; the quotient will be the number of cycles elapsed since the commencement of the era, and the remainder the golden number. *See* GOLDEN NUMBER.

Table of Gregorian Epacts.

Golden Number.	Epact.	Golden Number.	Epact.	Golden Number.	Epact.
I.	0	VIII.	17	XV.	4
II.	11	IX.	28	XVI.	15
III.	22	X.	9	XVII.	26
IV.	3	XI.	20	XVIII.	7
V.	14	XII.	1	XIX.	18
VI.	25	XIII.	12	I.	0
VII.	6	XIV.	23		

EPA'NALE'PSIS. (From the Greek preposition ἐπι, and ἀναλαμβανω, *I take up*.) In Rhetoric and Composition, a figure by which the word which begins the sentence is repeated at the end of it: "Judge not, that ye be not judged."

EPAU'LE. In Fortification, the shoulder of the bastion, or the angle made by the face and flank.

EPAU'LEMENT. A side work hastily raised to cover the cannon or men: also used for a demi-bastion, consisting of a face and flank; or for the redoubts made on a right line.

EPAULETTES. (Fr.) Distinguishing ornaments worn both by military and naval officers. In the different armies of the German states ensigns are not allowed to wear epaulettes; and hence the phrase "to obtain epaulettes," is synonymous with "to become a lieutenant." In the British army all officers with the rank of captain upwards wear two epaulettes; all under that rank only one.

EPENE'TIC. (Gr. ἐπαινετικος, from ἐπαινος, *an encomium*.) The laudatory or "encomiastic" species of oratory: a branch of the Epideictic, according to the division of Aristotle's *De Rhetorica*. *See* PANEGYRIC.

EPE'NTHESIS. A figure of grammar, by which one or more letters are inserted in the middle of a word; as in the Latin *rettulit* for *retulit*. *See* METAPLASM.

EPHEBEI'UM. (Gr. ἐφηβος, *a youth*.) In Ancient Architecture, the building appropriated for the wrestling and exercises of youth till they had, on their arrival at manhood, the right to enter the gymnasium.

EPHE'BI. (Gr. ἐφηβοι, signifying *arrived at the age of puberty*.) Applied particularly to the Athenian youth between the ages of eighteen and twenty years.

EPHE'MERANS, *Ephemerinæ*. (Gr. ἐφημερος, *daily*.) A family of Neuropterous insects, having the genus *Ephemera* as the type. They are called day-flies, from the enjoyment of their last stage of existence being generally limited to twenty-four hours.

EPHE'MERIS. (Gr. ἐφημερις; ἐπι, *upon*, and ἡμερα, *day*.) An astronomical table showing the places of a celestial body for every day at noon. Ephemerides (the plural) of the planets are computed and published annually for most of the principal observatories of Europe. The most celebrated of these are our own *Nautical Almanac*, the French *Connaissance des Tems*, and the Berlin *Jahrbuch*.

EPHEMERIS, in Literature, is a collective name for reviews, magazines, and all kinds of periodical literature.

EPHIA'LTES. (Gr. ἐφαλλομαι, *I leap upon*; from the sensation of something leaping upon the breast.) The nightmare. This affection, consisting of horrid dreams, with a sensation of great pressure upon the body, and of fruitless endeavours to escape and call for help, is generally symptomatic of indigestion, or of over-distension of the stomach. For its relief opening medicine, and sometimes an emetic, are often required, and careful abstinence from all that promotes dyspepsia, especially supper eating.

E'PHOD. (Heb.) A species of ornament worn by the Hebrew priests. The ephod worn by the high priest, says Calmet, was richly composed of gold, blue, purple, crimson, and twisted cotton; and upon the part which came over his shoulders were two large precious stones, upon which were engraven the names of the twelve tribes of Israel, six names upon each stone. The ephods worn by the ordinary priests were of fine linen. (See *Exod.* xxxix.)

E'PHORI. (Gr. ἐφοροι.) In Ancient History, the title of a class of magistrates common to many of the Dorian states of Greece, but more particularly known in reference to the political constitution of Sparta. The Spartan ephors were five in number, and were elected annually from the body of the ruling caste, and not from any particular tribe. They originally seem to have exercised a jurisdiction over the Spartans in their civil concerns, the

limits of which it is not easy to define; but their power increased by degrees, till it became supreme in the state. Besides their judicial authority, they exercised a control over the functions of the kings and the senate, and sometimes recalled the former from their foreign expeditions, and demanded an account of their proceedings. The executive power likewise was almost wholly in their hands.

E'PIC. (Gr. ἔπος, *a verse.*) A poem of an elevated character, describing generally the exploits of heroes. This species of poetry claims a very ancient origin, and is universally allowed to be the most dignified and majestic to which the powers of the poet can be directed. There are various theories regarding the character of an epic poem; and while some critics claim this title exclusively for the *Iliad* and *Odyssey* of Homer, the *Æneid* of Virgil, and the *Paradise Lost* of Milton, others — and particularly the Germans — embrace in the catalogue of epic writers Scott, Byron, Pope, Moore, and Campbell. Epic poetry has often been compared to the drama; and the essential difference between them is, that description is the province of the former — action of the latter. The emotions which epic poetry excite are not so frequent and violent as those produced by dramatic composition; but they are more prolonged, and more developed by actual occurrences; for an epic poem embraces a wider compass of time and action than is admissible in the drama. History has generally supplied the best epic writers with themes; but a close attention to historical truth in the development of the story is by no means requisite. Fiction, invention, imagination, may be indulged in to an almost unlimited extent; provided always the poet be careful to preserve what the critics call unity, *i. e.* provided his work embrace an entire action, or have a beginning, a middle, and an end. This is the distinguishing characteristic of the great epic poems. The object of the *Æneid*, for instance, is the establishment of Æneas in Italy; and amidst all the ramifications of the poem, the great object is kept steadily in view, and every digression from the subject is made powerfully and directly conducive to the progress and development of the tale. According to Aristotle, who has been implicitly followed by Blair, the essentials of an epic poem consist in the recital of some great event in a poetical form, — the contrivance of a plot important in itself, and instructive in the reflections which it suggests, filled with suitable incidents, enlivened with a variety of characters and descriptions, and maintaining throughout propriety of character and elevation of style. But besides these essential ingredients in epic poetry, there are also what may be termed *accidentals*, in which none of the great epic poems are deficient. These are a prescribed and lengthened march, formal addresses, sustained pomp, episodes, and machinery. About the necessity and use of machinery (the introduction of supernatural beings) in an epic poem there are various opinions. The French critics consider it as essential to the constitution of an epic poem, alleging that no poem, though possessed of every other requisite, has any pretension to be ranked in the epic class unless the main action be carried on by supernatural beings. "On peut dire," says Bossu, "en un mot qu'il faut user de machines partout, puisque Homere et Virgile n'ont rien fait sans cela." To be convinced of the error of this critic, we have only to ask ourselves what it is, in the writings of Homer and Virgil, that pleases us most? Assuredly, as an ingenious writer has remarked, it is not the councils of Olympus, the wiles of Juno and Venus, or the "animis in cœlestibus iræ" (how beautifully soever these are all pourtrayed), that awake a chord of sympathy, even after a lapse of two thousand years, in the breast of every one who reads them; but it is the knowledge of human nature, and the pictures of human feeling which these poems display, that have made them a "κτημα εις αει,"— a work for all time, a possession for eternity. In a word, upon this head we may say, that while, on the one hand, the *observance* of all these rules regarding machinery *alone* will never constitute an epic poem; so, on the other, the absence or violation of them in the hands of a man of genius will never deprive it of that character.

If the epic is the highest, it is also the most difficult style of poetical composition, and that in which mediocrity is least endurable; and hence few of the writers of epics on the classical model have obtained a high reputation as national poets in any language. Virgil is the earliest imitator of Homer whose epic has been preserved, and the most successful. The other Greek and Latin epic poets contain passages of great beauty; but their poems, as wholes, are of an inferior order. In the English language we have only two epics which can be said to form part of the national literature, and those only in part framed on the classical model: the *Paradise Lost* and *Regained* of Milton. French epics, including even the *Henriade* of Voltaire, so famous in its time, have no place among the chefs-d'œuvre of the national literature. Of the great Italian poems, only one (the *Jerusalem Delivered* of Tasso) fulfils the conditions of an epic. The poem of Dante, however sublime in style, has no unity of event or action: those of Ariosto, and the other Romanzieri, form a class distinguished from the epic by the mixture of the serious and ludicrous. The *Italia Liberata* of Trissino is simply pedantic. The old German and Spanish national poems, — the *Romance of the Cid*, and the *Niebelungen-Lied*, especially the latter, which is closely confined to the conduct of one great action, — although the work of writers unskilled in classical literature, deserve the title of epic as truly as those of Homer. There is a brief but masterly exposition of the origin and distinguishing characteristics of epic poetry in the *Penny Cyclopædia*, with reference to the chief German authorities on this subject.

EPICA'RIDANS, *Epicarides.* (Gr. ἐπι, *upon*, and καρις, *a shrimp.*) A family of Isopodous or equal-footed Crustaceans, which are parasitic upon shrimps.

EPICE'DIUM. (Gr. ἐπι, and κηδος, *grief.*) In Poetry, an elegiac poem on the occasion of a funeral solemnity in honour of some deceased person.

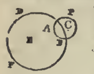
EPICRA'NITIS. (Gr. ἐπικραινω, *I finish.*) In Ancient Architecture, a tile forming the cyma of the cornice. The angular stone forming the vertex of the pediment was called the angular epicranitis. The term is used in the celebrated Athenian inscription brought to this country by Dr. Chandler, and now in the British Museum.

EPICURE'ANS. Followers of the tenets of Epicurus, a philosopher who lived from B. C. 337 to B. C. 270, and taught during the latter half of his life at Athens. The name of Epicurean has become the general designation of those who, either theoretically or practically, make pleasure the chief end of life and the standard of all virtue. Of the genuine doctrines of Epicurus himself we have notices in the work of Diogenes Laertius, who has preserved to us fragments of his very voluminous writings: but for these remains we should be at a loss, amid the conflicting statements of his friends and enemies, how to judge of his character as a man and a philosopher. The private character of Epicurus has, we doubt not, been unjustly aspersed; it will be found, however, on a careful examination of his system, that his merits as a philosopher have been as undeservedly extolled. Epicurus was the first philosophical teacher who deserted the lofty idea of science which Plato and Aristotle had striven to develop. Truth is, with him, no longer an object worth pursuing for its own sake, but only in so far as it contributes to the peace of mind of its possessor. Hence, though he retains the threefold division of philosophy into ethics, physics, and dialectics (in Epicurean language, canonic), he assigns the two latter a place subordinate to the first, and bestows on them a cursory and heedless mode of treatment.

We should greatly wrong Epicurus if we represented the gratification of the sensual appetites to be the object proposed by him to the wise man. The happiness which he regards as the true end of existence is rather a species of quietism, in which the philosopher, protected by his knowledge from all fear of injury from the powers of nature, and by the laws from the assaults of his fellow-creatures, holds himself open to all the pleasurable sensations which the temperate indulgence of his ordinary appetites, the recollection of past enjoyments, and the anticipation of future, are sufficient abundantly to furnish. In order to support his imaginary wise man in this tranquillity, he deemed it necessary to show that the apprehensions which beset mankind, of death, of the power and anger of the gods, and the like, are wholly unfounded. For this purpose he made use of the physical doctrine of Democritus; a system of atomic materialism, which makes all existences to arise from the concourse of minute particles of matter — the soul among the number, which is consequently, at the moment of death, resolved into its constituent elements. The mental philosophy of Epicurus was of a similar stamp: all our mental powers are resolved into sensation, immediate or recollected; and sensation, under both its forms, consists in the influx of certain extremely fine films, which are perpetually, as it were, sloughed from external objects, and find their way through the organs of sense to the soul. The gods of the Epicureans bear no relation to any part of their system: they are beings sprung, like men, from the concourse of atoms, and differing from them only in their superior blessedness and tranquillity, shown in their entire aloofness from the care and government of the world. The followers of Epicurus were numerous, especially among the Romans. Little more, however, than their names are recorded; with the exception of Lucretius, who, in his well-known poem, *De Rerum Naturâ*, illustrates and defends the physical and religious tenets of his master. In modern times, Gassendi, an atomic philosopher of the 17th century, has published an able statement of the Epicurean system, under the title of *Syntagma Philosophica Epicuri.* (See also *Diogenes Laërtius, Vit. Phil.* l. x.; and Cicero's philosophical writings generally: also *Ritter, Gesch. der Philos.* b. x. And for a list of the Epicureans, *Fabricii Bibliotheca Græca*, vol. iii. ed. Harles.)

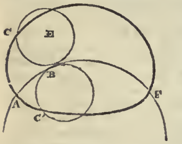
EPICY'CLE (Gr. ἐπι, *upon*, and κυκλος, *circle*), in the Ancient Astronomy, is a circle having its centre on

the circumference of another circle. It was a favourite axiom of the Greek astronomers, that all the celestial motions must be circular and uniform. The phenomena of the stations and retrogradations of the planets were apparently inconsistent with this supposition; and in order to explain them, Apollonius of Perga imagined the ingenious apparatus of *epicycles* and *deferents*. He supposed



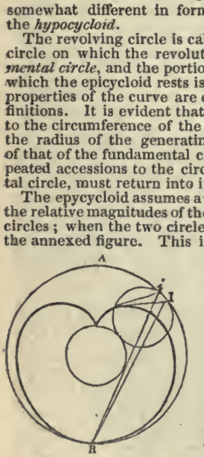
the planet P to move uniformly in the small circle or *epicycle* P A B, the centre of which is carried uniformly forward along the circumference of the large circle or *deferent* C D F, of which the earth occupies the centre E. Hipparchus, having discovered the eccentricity of the solar orbit, supposed the motions to be performed in eccentric circles. Ptolemy, the celebrated founder of the system which astronomers followed till the days of Copernicus, adopted the hypotheses both of Apollonius and Hipparchus; that is, he supposed the earth E to be placed at a small distance from the centre of the deferent circle (which consequently was called an eccentric), and the planet to move uniformly in the epicycle, the centre of which also moves uniformly in the deferent. By means of these suppositions, and by assigning proper ratios (determined by observation) between the radius of the deferent and the radius of the epicycle, and also between the velocity of the planet in its epicycle and the velocity of the centre of the epicycle on the deferent, he was enabled to represent with considerable accuracy, indeed with all the accuracy which the observations of that time required, the apparent motions of the planets, and particularly the stations and retrogradations which formed the principal object of the researches of the ancient astronomers. As a first step towards connecting the two sciences of astronomy and geometry, the system of epicycles does infinite honour to its inventors; and it ought to be borne in mind that it was never given out by Ptolemy as any thing else than a mere hypothesis for representing the apparent celestial motions, or, as he expresses it, for *saving* the appearances.

E'PICY'CLOID (Gr. επικυκλος, and ειδος, *form*), in Geometry, is a curve line which is generated by the revolution of a point in the circumference of a circle which rolls on the circumference of another circle either externally or internally. Thus, let the circle whose centre is E touch the circle A B F at the point A, and roll along the outside of the circumference; the point of original contact C, carried round till it return again to the circumference at F, will trace an epicycloid. If the circle revolve on the inside of the circumference, the curve traced out by the point C' will still be of the same kind, though somewhat different in form. This is sometimes called the *hypocycloid*.



The revolving circle is called the *generating circle*, the circle on which the revolution is performed the *fundamental circle*, and the portion of the fundamental circle on which the epicycloid rests is called its *base*. Some of the properties of the curve are easily deduced from these definitions. It is evident that the whole base A F is equal to the circumference of the generating circle; and when the radius of the generating circle is any aliquot part of that of the fundamental circle, the epicycloid, after repeated accessions to the circumference of the fundamental circle, must return into itself at the same point A.

The epycycloid assumes a variety of forms, according to the relative magnitudes of the fundamental and generating circles; when the two circles are equal, its form is that of the annexed figure. This is one of the caustic curves; for rays of light, issuing from a luminous point R in the circumference of a circle R I A, and reflected from any points I *i* in the circumference, are tangents to the curve; consequently all the reflected rays intersect in the curve which is thus traced out by the assemblage of brilliant points. When the radius of the generating circle is only half that of the fundamental circle, the exterior epicycloid forms the caustic of parallel rays. In this case the interior epicycloid becomes a straight line, the point C tracing out the diameter of the fundamental circle.



It is a remarkable property of epicycloids, that when the diameter of the generating circle is any aliquot part of the diameter of the fundamental circle, they are algebraic curves; and the whole epicycloidal circuits are capable of being expressed geometrically in terms of the diameters of those circles. Thus, let the radius of the generating circle be 1, and the radius of the fundamental circle n; then the length of the complete arc of the exterior epicycloid is expressed by the formula $8\left(\frac{n+1}{n}\right)$, and of the interior epicycloid by $8\left(\frac{n-1}{n}\right)$. In this case also the epicycloidal spaces, or areas, are expressible in terms of the areas of these circles; the surface of the exterior epicycloid being $\frac{3n+2}{n}$ times, and that of the interior epicycloid $\frac{3n-2}{n}$ times the area of the generating circle In all cases the epicycloid, as above defined, is rectifiable; but when the tracing point is not situated in the circumference of the generating circle, but any where in its plane within or without it, the curve is of a different nature, and the above properties no longer hold true. In this case the exterior curve is usually called the *epitrochoid*, and the interior the *hypotrochoid*.

The epicycloid was invented by the celebrated Danish astronomer Romer, the discoverer of the progressive motion of light, who proposed this curve, about the year 1674, as the proper form of the teeth of wheels, in order to destroy the friction. Newton, in the first edition of the *Principia*, gave its rectification; and Halley, in the *Philosophical Transactions*, No. 218., showed how its quadrature depends on that of the generating circle. The other principal properties of the curve were discovered and demonstrated by John Bernoulli.

The term *epicycloid* is applied to other curves than the above, but described in an analogous manner. If the revolving circle forms a constant angle with the plane of the fundamental circle, the curve traced out is called a *spherical epicycloid*. If an ellipse is made to roll on another ellipse, the generating point traces an *elliptic* epicycloid, &c.

EPIDE'MIC. (Gr. επι, *upon*, and δημος, *people*.) An infectious or contagious disease, which attacks many people at the same period and in the same country, "rages for a certain time, and then gradually diminishes and disappears, to return again at periods more or less remote." Thus influenza, scarlet fever, measles, &c., frequently appear as *epidemics;* that is, are found to prevail in certain parts of a country, while the adjacent districts are wholly free from their ravages. It is essential to the medical notion of an *epidemic* that it be of a temporary, in contradistinction to a permanent character. It differs from *endemic*, inasmuch as the latter class of diseases are of a permanent nature, and prevail only among certain people, and in certain districts.

EPIDE'RMIS. (Gr. επι, and δερμα, *the true skin.*) In Anatomy, the cuticle or scarf skin. It is an albuminous membrane.

EPIDERMIS. In Botany, the cellular integument, or the exterior cellular coating of the bark, or leaf, or stem of a plant. It is composed of cells compacted together into a stratum, varying in thickness in different species, and is often readily separable by gentle violence. It is believed to be intended by nature as a protection of the subjacent parts from the drying effects of the atmosphere.

E'PIDOTE. (Gr. επιδιδωμι, *I increase.*) A mineral which has received a great variety of names. It occurs crystallized, massive, and granular; its usual colours are various shades of green; its structure is generally fibrous. It is a triple silicate of alumina, lime, and iron. It occurs in most parts of Europe, in America, and in the East Indies. "L'épidote emprunte même des dimensions de sa molécule un caractère particulier; il consiste en ce que l'un des côtés de la base de cette molécule est plus étendu que l'autre, en sorte que cette base est un parallélogramme allongé, au lieu que dans les autres substances (actinote, amphibole, &c.) la figure de la base est d'un nombre. C'est de cette espèce *d'accroissement* que j'ai tiré le nom *d'épidote*." (*Hauy.*)

EPIGÆ'OUS. (Gr. επι, *upon*, and γη, *the earth.*) In Botany, a term used in describing the situation of bodies to denote any one growing close to the earth.

EPIGA'STRIC REGION (Gr. επι, and γαστηρ, *the stomach*), is that part of the abdomen which is over the stomach. It is also called the epigastrium.

E'PIGE'NESIS. In Physiology. *See* EVOLUTION.

EPIGLO'TTIS. (Gr. επι, and γλωττα, *the tongue.*) An oval cartilage at the root of the tongue, which closes upon the superior opening of the larynx; its superior extremity is loose, and elevated by its own elasticity: it closes the aperture of the larynx when the tongue is drawn back in the act of deglutition. Its base has a ligamentous attachment to the base of the tongue, the thyroid cartilage, and the os hyoides.

EPI'GONI. (Gr. επι, in the sense of *after*, and γιγνομαι, *I am born.*) The collective appellation of the sons of the seven Greek princes who conducted the first war against Thebes without success. The war subsequently undertaken by the Epigoni to avenge the defeat of their forefathers is celebrated in history. Their capture of Thebes forms the theme of Wilkie's epic poem, the *Epi-*

goniad, which was published about the middle of the last century, and procured for its author great reputation.

E'PIGRAM. (Gr. ἐπίγραμμα, *an inscription.*) In Poetry, a short poem or piece in verse, which has only one subject, and finishes by a witty or ingenious turn of thought; or, to use a more general definition, an interesting thought represented happily in a few words.

The first of these definitions, although tolerably correct as to the modern epigram, differs, as it will be seen, widely from the original sense of the word in Greek. The Greek epigram was, in the first instance, a short collection of lines actually inscribed on a monument, statue, fountain, &c.; and the word was thence transferred to such short poems as might serve for inscriptions: of such the collection termed the *Greek Epigrams* is almost wholly composed. Their general characteristic is perfect simplicity, and the seemingly studied absence of that *point* which characterizes the modern epigram. They are almost wholly in one form of metre, the elegiac.

In the poetry of classical Rome, the term epigram was still somewhat indiscriminately used to designate short pieces in verse; but the works of Catullus, and still more the well-known collection of the *Epigrams of Martial*, contain a great number which present the modern epigrammatic character; and Martial has, in fact, afforded the model on which the modern epigram has been framed. In this class of composition, and especially where the turn of thought is satirical, the French writers have been far more successful than those of any other nation; and the term "piquant" seems expressly invented to designate the peculiar force of those epigrammatic sallies of fancy of which their literature is full. (See Dr. Johnson's learned *Essay on Epigrams.*)

E'PIGRAPH (Gr. επιγραφω, *I inscribe*), also termed *Motto*. In Literature, a citation from some author, or a sentence framed for the purpose, placed at the commencement of a work or of its separate divisions.

EPI'GYNOUS. (Gr. επι, *upon*, and γυνη, *a female.*) A term used in botany to denote any organ growing upon the summit of the ovarium.

E'PILEPSY. (Gr. επιλαμβανω, *I seize upon.*) This disease is also called the *falling sickness*, from the suddenness of its attack. It is attended by convulsive stupor and frothing at the mouth. It comes on by fits, which after lasting a certain time go off, generally leaving a degree of lassitude and drowsiness. Where epilepsy is symptomatic of irritation in the primæ viæ, from worms, or indigestible and noxious food or poisons, or when it arises from the suppression of long-accustomed evacuations, the treatment is sufficiently obvious; so also in cases where it results from a blow, wound, or fracture, or from diseased bone, it may be relieved by proper surgical aid. Plethoric habits require lowering, and debility indicates the use of tonics. The disease, however, is always indicative of something essentially wrong in the nervous system; and where it arises from hereditary disposition, or comes on about the age of puberty, where the fits are frequent, and cannot be referred to any apparent cause, an unfavourable opinion must be formed respecting its termination, which, if not in apoplexy, is commonly in mental alienation or imbecility. Yet, the most unpromising cases have in a few rare instances ended well; that is, they have not recurred after violent pains, or eruptive disorders. It sometimes happens that certain symptoms precede the attack; and among them a sense of coldness proceeding from some part of the body towards the head, and called *aura epileptica*, with palpitation, flatulency, and slight stupor, are the most common. In such cases a brisk emetic, a large dose of opium and ether, a cold bath where it may be ventured upon, or any thing which produces a sudden shock upon the system, has prevented the fit. The most effective remedial treatment seems to be that which is directed to the diminution of nervous irritability by sedatives and tonics: among the former opium, ether, henbane, hemlock, and more lately morphia and strichnia, have been recommended; and as tonics bark, quinia, cascarilla, valerian, and some metallic salts, such as sulphate of iron, zinc, or copper, arseniate of potash, or the arsenical solution, and especially nitrate of silver; but the chance of permanently disfiguring the patient by the leaden hue which this last salt often communicates to the skin, should induce practitioners to be most scrupulous in the selection of this remedy. It is said that a violent scald or burn, or great alarm, as from a fire, a fall, and such accidents, have sometimes relieved the system of this horrible complaint; and hence perhaps the superstitious notions which have attached to its cure by charms.

During an epileptic fit, nothing can be done for the relief of the sufferer except taking care that he does not injure himself, and relieving him of any part of his dress which may tend to compress the vessels of the head; the paroxysms, however, are most frequent in the night.

E'PILOGUE. (Gr. επιλογος.) In Dramatic Poetry, the closing address to the audience at the end of a play.

EPI'PHANY. (Gr. επιφανης, *manifest.*) A church festival, signifying the manifestation of Christ, and referring to the appearance of the star which announced our Saviour's birth to the Gentiles. It is observed on the 5th of January, being the twelfth day from Christmas.

EPIPHONE'MA. (Gr. επι, *upon*, and φωνεω, *I speak.*) In Rhetoric and Composition, a short reflection added by way of corollary, or passing remark, to the end of a course of narrative or reasoning.

EPI'PHORA. (Gr. επι, *upon*, and φερω, *I bear.*) In Rhetoric, the emphatic repetition of a word or series of words at the end of several sentences or stanzas. The finest instance of this figure with which we are acquainted in modern oratory occurs in Fox's defence of himself and his measures in the House of Commons after the dissolution of the Coalition Ministry. Anaphora is a similar repetition at the beginning of several sentences.

EPI'PHORA. A disease occasioned by a superabundant secretion of tears.

EPIPHY'LLOUS. (Gr. επι, and φυλλον, *a leaf.*) In Botany, something inserted upon a leaf.

EPI'PHYSIS. (Gr. επι, *upon*, and φυσις, *nature.*) A process of a bone separated at first by a layer of cartilage from that to which it is attached.

EPIPLOCE'LE. (Gr. επιπλοον, *the omentum*, and κηλη, *tumour.*) A hernia or rupture formed by a protrusion of the omentum.

E'PIPLOON. (Gr.) The *omentum*.

EPISCE'NIUM. (Gr. επι, *upon*, and σκηνη, *a scene.*) In Ancient Architecture, the upper order of the scene in the theatre.

EPI'SCOPACY. (Gr. επισκοπος, *an overseer.*) The government of a church by three distinct orders of ministers — bishops, priests, and deacons. The nature of the argument upon which this constitution is best defended will be most clearly seen in a quotation from Mr. Short's *History of the English Church*. Speaking of the points at issue between the Presbyterians and the Church party in the reign of Elizabeth, he says, "Were there three distinct orders in the primitive church? and if so, was the right and office of ordaining peculiar to the highest of these?" He then proceeds to argue thus: — "In the apostolical history, as contained in the New Testament, these questions are not clearly answered, and there is much indistinctness about the names of bishop and priest or elder; but if we suppose, by way of hypothesis, that there were bishops, priests, and deacons, we shall find no statements which cannot be easily reconciled with the supposition. As we proceed with ecclesiastical history, those same traces become more decisive, till we find that at an early period the questions are both answered in the affirmative; and we infer, therefore, that unless it can be shown that a change in this particular took place, we may presume that the same ecclesiastical constitution existed from the time of the apostles. A Presbyterian might argue that in the apostolical history of the New Testament there is nothing which militates against the hypothesis of the two orders only, at least nothing which proves the point; that St. James might have been the chief elder, the moderator of the church of Jerusalem; that Titus and Timothy might have held no higher office than that of dean in a cathedral church, or archdeacon in a diocese; and that as the presbytery had the power of ordaining, they, as its superintendants, were directed by St. Paul to set all things in order. But then this hypothesis does not account for the introduction of episcopacy, without even a hint from the historians that any alteration in the church government was effected. When to this it is added, that there never existed a church without episcopacy till the Reformation, the proof seems as strong as moral proof can be that it is most probable that episcopacy is derived from the times of the apostles." He adds in a note — "The argument concerning the name of bishop is frequently mistaken. There is no doubt that ἐπίσκοπος is equivalent to πρεσβύτερος in the New Testament; but then the terms used in the New Testament for bishop are ἀπόστολος, or ἄγγελος. The concession, therefore, of the use of the name ἐπίσκοπος proves nothing. The Presbyterian is forced to say, that the order equivalent to that of the apostles does not now exist in the church, and to explain ἄγγελος by *the chief pastor of the church.* So that the argument from the names is rather in favour of episcopacy." It will be observed that this defence mainly relies upon the argument from antiquity and immemorial usage; and this is the authority to which the episcopalian always pays the highest regard when the Scriptures do not appear to be decisive. But the Presbyterians and Independents very generally take a different ground, and argue in the words of Dr. Maclaine, the translator of Mosheim — "that Christ, by leaving this matter undetermined, has of consequence left Christian societies a discretionary power of modelling the government of the church in such a manner as the circumstantial reasons of times, places, &c. may require; and therefore the wisest government of the church is the best and the most divine; and every Christian society has a right to make laws for itself, provided that these laws are consistent with charity and peace, and with the fundamental doctrines and principles of Christianity."

E'PISODE. In Poetry. From the Greek ἐπεισόδιον,

which in its original sense denotes those parts of a classical drama which are between the entrances, εἴσοδοι, of the chorus; and thence, by analogy, has the signification which has adhered to the derivative word in modern use,— an incidental narrative or digression in a poem, more or less connected with the main plot, but not essential to its development.

EPISPA'STIC. (Gr. επισπαω, *I draw upon.*) A term applied to substances which raise a blister upon the skin.

E'PISPERM. (Gr. επι, *upon*, and σπερμα, *a seed.*) In Botany, the testa or integuments of a seed.

EPI'STATES. (Gr. επιστατης.) The title of the presidents of the two great councils of the Athenians, viz. the Ecclesia and the senate of the Five Hundred. They were both respectively elected from the number of the prohedri of the ecclesia and senate, and their office only lasted one day. The latter of these two officers had the post of the greatest trust, as in his hands were placed the keys of the citadel and public treasury.

E'PISTA'XIS. (Gr. επισταζειν, *to drop from.*) Bleeding at the nose. In young persons, and where it is produced by accidental causes, this is of no consequence; unless, indeed, it should be very profuse, and then the topical application of cold and of styptics, especially a strong solution of alum, or a plug of lint properly introduced, will check it; but when it occurs frequently in advanced life, and is independent of nasal disease, it is apt to indicate an alarming fulness of the vessels of the head. It is also a dangerous omen in disorders of great debility, and more especially in putrid fever.

EPISTHO'TONOS. (Gr. επισθεν, *forwards*, and τεινω, *I bend.*) A spasmodic affection, in which the body is bent forwards.

EPI'STLE. (Gr. ἐπιστολη.) The use of this word is now confined in our language to the designation of those written addresses by apostolical writers to their Christian brethren which are contained in the canon of Scripture: a few others, either spurious or of high antiquity, although not recognized among inspired writings, are also so denominated. The Epistles of St. Paul, and others contained in the volume of the New Testament, are not arranged according to their date, but, in all probability, according to the views which those who arranged the canon entertained of the relative importance either of the writings themselves, or of the parties to whom they are addressed Thus the Epistles of St. Paul to the different churches, and the Catholic Epistles of St. John (*i.e.* addressed to the universal church), are ranked before the Epistles of those saints to individual Christians. An exception to this rule is to be found in the Epistle to the Hebrews, which is placed last among those of St. Paul, and seems to have been admitted into the canon at a comparatively recent period. The practice of reading a portion of an Epistle in the service of the church is extremely ancient, and said to be noticed by Justin in his *First Apology*.

E'PISTY'LIUM. (Gr. επι, *upon*, and στυλος, *a column.*) In Architecture, the same as *architrave*, which see.

E'PITAPH. (Gr. επι, and ταφος, *a tomb.*) Literally an inscription on a tomb. As has been well observed, inscriptions in honour of the dead are perhaps as old as tombs themselves; though they were by no means bestowed in such profusion in ancient as in modern times. Among the Greeks, for instance, this honour was paid only to the tombs of heroes, as in the case of Leonidas and his gallant comrades. (*Her.* vii. 228.) The Romans were the first to deviate from this course. Every Roman family who consecrated a tomb to their relations had the privilege of inscribing an epitaph thereon; and as their tombs were usually situated on the highway, the attention of passers-by was sought to be arrested by the words "sta viator;"—the formula with which all their epitaphs were prefaced. But how much soever the epitaphs of the ancient Greeks and Romans differed in point of number, there were three qualities which they possessed in common—brevity, simplicity, and familiarity; qualities which a modern critic, Boileau, has pronounced to be indispensable in this species of writing.

At what period sepulchral inscriptions came into use in England, has not been precisely ascertained; though there can be little doubt that this practice was introduced by the Romans at the period of their invasion of Britain. During the first twelve centuries of the Christian era, the monumental inscriptions of this country were all written in Latin. About the 13th century, the French language was adopted, and continued to be used for this purpose till the middle of the 14th century; at which time monumental inscriptions in the vernacular tongue became common, though the clergy and learned of that time, as might have been expected, still preferred the Latin, as their more familiar idiom. The modern English, French, and German epitaphs, of which several collections have been made, are infinitely more numerous than those of any time or nation, and exhibit every variety of style and sentiment; from the most chaste and majestic gravity, impressive tenderness, and laconic terseness, to the most puerile epigrammatic conceits, pointed satire, and heraldic prolixity. It would be out of place here to give specimens of all the various kinds of epitaphs included in this category; but we cannot refrain from citing, in illustration of our assertion, one or two instances, exhibiting each in an eminent degree the different characteristics of the class to which it belongs.

Epitaph on the Countess of Pembroke, by Ben Jonson.

Underneath this sable hearse
Lies the subject of all verse;
Sidney's sister, Pembroke's mother:
Death, ere thou canst find another
Good and fair and wise as she,
Time shall throw a dart at thee.

Epitaph on Robespierre.

× Passant, ne pleure point mon sort;
Si je vivais, tu serais mort!

× Passer-by, weep not for me,
Were I alive thou wouldst not be.

Epitaph on a French General.

Siste, viator; heroem calcas!
Stop, traveller; thou treadest on a hero!

E'PITHALA'MIUM. (Gr. ἐπιθαλαμιον.) A nuptial song, sung by a chorus of boys and girls when the bride and bridegroom entered the bridal chamber, and again on the first morning after the marriage. This was the custom in Greece, which was somewhat varied at Rome, where the chorus consisted of girls only, who sang before the door of the nuptial chamber till midnight. The most perfect examples of this species which antiquity has left us are by Theocritus and Catullus.

E'PITHET (Gr. ἐπίθετον, *something imposed upon another*), in Rhetoric and Composition, denotes a term employed in an adjective sense to express an attribute or quality of another substantive term. The abundance and the propriety of epithets form peculiar characteristics of various poetical styles. In the strict rhetorical sense, epithets are only such adjectives as convey a notion already implied in the noun substantive itself, and add nothing to the sense. Thus, the "glorious" sun is a mere epithet; while the "rising" or the "setting" sun would, as conveying some additional idea into the sense of the passage, not be considered as epithets. The former sort, however, are sometimes called in disparagement by writers on rhetoric "otiosa," or idle epithets.

EPITI'THIDES. (Gr. επι, and τιθημι, *I place.*) In Architecture, the crown or upper mouldings of an entablature.

EPI'TOME. (Gr. επιτέμνω, *I cut short.*) In Literature, an abridgment: a work in which the contents of a former work are reduced within a smaller space by curtailment and condensation. In the later classical period, extending through the declining age of the Western Empire, the practice of epitomizing the writings of older writers, especially in history, became very prevalent; and while some regard the works of Justin, Eutropius, and similar writers as having preserved to us much historical knowledge which would otherwise have been lost, others have maintained that these laborious compilers have done great disservice to literature, inasmuch as the voluminous works which they abridged being superseded by their more popular and cheaper compendia, in an illiterate age, have from that cause for the most part perished. *See* Abridgment.

EPIZO'ANS, *Epizoa*. (Gr. επι, *upon*, and ζωον, *animal.*) The name of a class of parasitic animals, which chiefly infest fishes, and of which the Linnæan genus *Lernæa* is the type.

E'POCH. (Gr. ἐποχη, from επεχω, *I stop.*) In Chronology, a fixed point of time from which dates are numbered, or at which a new computation begins. It is consequently the commencement of an æra. *See* Æra.

E'PODE. (Gr. επωδος, *something added to the ωδη, or ode.*) In the strophic choruses of the Grecian drama, the last portion following the strophe and antistrophe is so called. The name of *Epodes*, applied to a book of Horace's poems, merely signifies additional or supplementary odes.

EPOPEE. *See* Epic.

E'POPT. (Gr. εποπτης, *inspector.*) A functionary of the Eleusinian Mysteries, which see.

EPROUVE'TTE. In Gunnery, a machine for proving the strength of gunpowder. A small gun is attached to a frame, which is suspended from a horizontal rod, about which it oscillates like a pendulum. On the gun being fired, the recoil causes the frame to swing; and the force of the recoil is measured by the angle which the frame describes. In this manner the relative strength of different sorts of gunpowder is ascertained.

E'PSOM SALT. Sulphate of magnesia; formerly obtained by evaporating the water of certain springs at Epsom in Surrey.

EPU'LIS. (Gr. επι *upon*; οὖλα, *the gums.*) A small tubercle on the gums.

EPULO'TIC. (Gr. επι, and οὐλη *a scar.*) Applications which promote the skinning over of sores; hence the *epulotic ointments* of old pharmacy.

E'QUANT, in the Ptolemaic Astronomy, denotes a circle which was conceived to be described in the plane of the deferent or eccentric, for regulating and adjusting certain motions of the planets, and reducing them to easier calculation.

EQUA'TIONS, ALGEBRAICAL. An algebraical equation is an expression of equality between two quantities involving the ordinary symbols of algebra in any manner whatever. The "Theory of Algebraical Equations" forms an important subject or department of analysis, and is always understood to embody the discussion of equations when presented in their most convenient form for solution; and its great object is to develop the properties and to evolve the values of the real and imaginary roots. The equations are supposed to be cleared from radicals, and are classed in degrees according to the highest exponent of the unknown quantity.

Thus, if x denote the unknown quantity, and c_0, c_1, c_2, c_3, &c. the given numbers or coefficients;

$c_1 x + c_0 = 0$ is a *simple equation*, or an equation of the *first* degree;

$c_2 x^2 + c_1 x + c_0 = 0$ is a *quadratic*, or an equation of the *second* degree;

$c_3 x^3 + c_2 x^2 + c_1 x + c_0 = 0$ is a *cubic equation*, or an equation of the *third* degree;

$c_4 x^4 + c_3 x^3 + c_2 x^2 + c_1 x + c_0 = 0$ is a *biquadratic equation*, or an equation of the *fourth* degree, &c. &c.

And $c_n x^n + c_{n-1} x^{n-1} \ldots + c_2 x^2 + c_1 x + c_0 = 0$ is an equation of the nth degree.

We shall here consider two or three of the most important and useful general properties of an equation of the nth degree.

The complete solution of every equation of the nth degree must always comprise as many as n roots, real and imaginary, the imaginary roots being of the forms $p + q\sqrt{-1}$, $p - q\sqrt{-1}$. When a real root is substituted for x in the equation, the involved terms must counteract one another, and cause the result to vanish; and when an imaginary root is substituted for x in the equation, both the real and imaginary portion of the result must separately vanish. If the substitution of $p + q\sqrt{-1}$ causes both the real and imaginary parts to vanish, it is evident that the substitution of $p - q\sqrt{-1}$ will have the same effect, since the result will only differ from that of the former in the imaginary terms having changed all their signs. It follows from this remark that if an equation possesses a root of the form $p + q\sqrt{-1}$, it must likewise possess a corresponding imaginary root of the form $p - q\sqrt{-1}$. The roots $p + q\sqrt{-1}$, $p - q\sqrt{-1}$ are called a pair of imaginary roots; and as these roots must thus enter equations in pairs, every equation must have an even number of impossible roots, or else none at all.

Suppose the roots of an equation to be all real, and let them be denoted by $r_1, r_2, r_3 \ldots$ &c.; then the equation will in all cases be produced by multiplying together the factors $x - r_1$, $x - r_2$, $x - r_3$, &c. The equation may therefore be put in the form,

$$(x - r_1)\,(x - r_2)\,(x - r_3) \ldots \&c. = 0 \ldots \text{(A)}.$$

If, however, the equation likewise contains pairs of imaginary roots, $p + q\sqrt{-1}$, $p - q\sqrt{-1}$, $p' + q'\sqrt{-1}$, $p' - q'\sqrt{-1}$, &c., it will also embody the factors $(x - p - q\sqrt{-1})\,(x - p + q\sqrt{-1})\,(x - p' - q'\sqrt{-1})\,(x - p' + q'\sqrt{-1})$ &c.; or $\left((x - p)^2 + q^2\right)\left((x - p')^2 + q'^2\right)$ &c.; and will consequently take the form,

$$(x - r_1)\,(x - r_2)\,(x - r_3) \ldots \left((x - p)^2 + q^2\right)\left((x - p')^2 + q'^2\right) \ldots \&c. = 0 \ldots \text{(B)}.$$

The equation, when thus put in the form (A) or (B), is evidently satisfied when x is made equal to any one of the roots $r_1, r_2, r_3 \ldots p + q\sqrt{-1}$, $p - q\sqrt{-1}$, $p' + q'\sqrt{-1}$, $p' - q'\sqrt{-1} \ldots$ &c.; and the idea is very clearly conveyed how an equation of the nth degree may be fulfilled by n different roots, determined by equating the factors severally with *zero*.

If the factors of (A) be incorporated by actual multiplication, we shall derive expressions for the coefficients of the equation in terms of its roots. The operation will be as follows:

$$\begin{array}{l}
x - r_1 \\
x - r_2 \\
\hline
\begin{array}{r|l}
x^2 - r_1 & x + r_1 r_2 \\
- r_2 &
\end{array}
\end{array}$$

$$\begin{array}{l}
x - r_3 \\
\hline
\begin{array}{r|r|l}
x^3 - r_1 & x^2 + r_1 r_2 & x - r_1 r_2 r_3 \\
- r_2 & + r_1 r_3 & \\
- r_3 & + r_2 r_3 &
\end{array}
\end{array}$$

$$\begin{array}{l}
x - r_4 \\
\hline
\begin{array}{r|r|r|l}
x^4 - r_1 & x^3 + r_1 r_2 & x^2 - r_1 r_2 r_3 & x + r_1 r_2 r_3 r_4 \\
- r_2 & + r_1 r_3 & - r_1 r_2 r_4 & \\
- r_3 & + r_2 r_3 & - r_1 r_3 r_4 & \\
- r_4 & + r_1 r_4 & - r_2 r_3 r_4 & \\
& + r_2 r_4 & & \\
& + r_3 r_4 & &
\end{array}
\end{array}$$

By continuing the process we infer, generally, that for any equation in which the highest power of x has the coefficient unity, the coefficient of the second term is equal to the sum of the roots with the sign changed; that of the third term is equal to the sum of the products of every two roots; that of the fourth term is equal to the sum of the products of every three roots with the sign changed, &c. &c.; and the last term c_0, unaccompanied by x, is equal to the continued product of all the roots, with the proper algebraic sign when the degree of the equation is even, but with the sign changed when the degree is odd.

The consideration of an equation resolved into its simple factors (A) also, amongst other useful matters, suggests the method of eliminating a known root from an equation so as to descend to another equation of the next less degree, which contains the remaining roots. If r_1 be the known root, it is only necessary to divide the equation by the factor $x - r_1$; and in this operation the occurrence of no remainder will assure us that r_1 is in reality a true root of the equation. It will therefore be an advantage to ascertain a systematic plan by which the process of division by such a factor may be performed with facility. To preserve generality, suppose m to be any number that either may or may not be one of the roots of the equation,

$$c_n x^n + c_{n-1} x^{n-1} + c_{n-2} x^{n-2} \ldots + c_2 x^2 + c_1 x + c_0 = 0.$$

And on the equation being divided by $x - m$, suppose the quotient to be

$$c'_{n-1} x^{n-1} + c'_{n-2} x^{n-2} \ldots + c'_1 x + c'_0.$$

Then the actual work of the division will stand thus:

$$\begin{array}{l}
x - m\,\big)\, c_n x^n + c_{n-1} x^{n-1} + c_{n-2} x^{n-2} + \&c. \big(c'_{n-1} x^{n-1} + c'_{n-2} x^{n-2} + \&c. \\
\qquad c'_{n-1} x^n - m c'_{n-1} x^{n-1} \\
\hline
\qquad\qquad c'_{n-2} x^{n-1} + c_{n-2} x^{n-2} \\
\qquad\qquad c'_{n-2} x^{n-1} - m c'_{n-2} x^{n-2} \\
\hline
\qquad\qquad\qquad c'_{n-3} x^{n-2} + \&c.
\end{array}$$

By equating the several subtractions we hence derive the following relations for determining the coefficients c'_{n-1}, c'_{n-2}, &c.; viz.

$$\begin{aligned}
c'_{n-1} &= c_n \\
c'_{n-2} &= c_{n-1} + m c'_{n-1} \\
c'_{n-3} &= c_{n-2} + m c'_{n-2}, \ \&c. \\
c'_0 &= c_1 + m c'_1
\end{aligned}$$

and the remainder, $p = c'_0 + m c'_0$.

Thus it appears that the coefficient of the pth term of the depressed equation is successively found by adding m times the coefficient of the preceding term to the pth term of the original equation. As an example, let it be required to divide the equation $3x^3 + 3x^2 - 48x + 60 = 0$ by $x - 3$.

$$\begin{array}{lrrrr}
\text{Coefficients proposed,} & 3 & +\ 3 & -\ 48 & +\ 60 \\
 & & +\ 9 & +\ 36 & -\ 36 \\
\cline{2-5}
 & \multicolumn{3}{r|}{3x^2 + 12x - 12} & +\ 24 \\
 & \multicolumn{3}{r|}{\text{Quotient.}} & \text{Remainder.}
\end{array}$$

Again, let it be required to divide the same equation by $x - 2$.

$$\begin{array}{lrrrr}
\text{Coefficients proposed,} & 3 & +\ 3 & -\ 48 & +\ 60 \\
 & & 6 & +\ 18 & -\ 60 \\
\cline{2-5}
 & \multicolumn{3}{r|}{3x^2 + 9x - 30} & 0 \\
 & \multicolumn{3}{r|}{\text{Quotient.}} & \text{Remainder.}
\end{array}$$

Here the existence of no remainder points out 2 to be a root of the proposed equation, and $3x^2 + 9x - 30 = 0$, or $x^2 + 3x - 10 = 0$ to be the depressed equation containing the other two roots, which are therefore 2 and -5.

This expeditious method of dividing an equation by a simple factor may be employed with advantage in transforming an equation into another, whose roots shall differ from those of the former by any given quantity. Let the proposed equation be

$$c_4 x^4 + c_3 x^3 + c_2 x^2 + c_1 x + c_0 = 0.$$

Suppose that $x = x' + r$, and the substitution of this value instead of x will manifestly give a transformed equation, the roots of which will be less than those of the former by the quantity r; and this transformed equation will be of the form,

$$c_4 x'^4 + c'_3 x'^3 + c'_2 x'^2 + c'_1 x' + c'_0 = 0.$$

Now, if $x - r$ be put for x', this must return to the original equation; and hence the proposed equation is the same as $c_4 (x - r)^4 + c'_3 (x - r)^3 + c'_2 (x - r)^2 + c'_1 (x - r) + c'_0 = 0$. The following process of successive division,

which may be rapidly executed by the foregoing rule, thus furnishes a simple method of arriving at the sought coefficients:

$$\begin{array}{l}
x-r)\overline{c_4(x-r)^4+c'_3(x-r)^3+c'_2(x-r)^2+c'_1(x-r)+c'_0} \\
x-r)\overline{c_4(x-r)^3+c'_3(x-r)^2+c'_2(x-r)+c'_1} \mid \text{rem. } c'_0 \\
x-r)\overline{c_4(x-r)^2+c'_3(x-r)+c'_2} \mid \text{rem. } c'_1 \\
x-r)\overline{c_4(x-r)+c'_3} \mid \text{rem. } c'_2 \\
\quad\quad c_4 \mid \text{rem. } c'_3
\end{array}$$

Example: Let it be required to transform the equation $x^4+5x^3+4x^2+3x-105$ into another, whose roots shall be 2 less than those of the proposed equation.

	c_3	c_2	c_1	c_0
1	+ 5	+ 4	+ 3	− 105 (2
	2	+ 14	+ 36	+ 78
1	+ 7	+ 18	+ 39	− 27 = c'_0
	2	+ 18	+ 72	
1	+ 9	+ 36	+ 111 = c'_1	
	2	+ 22		
1	+ 11	+ 58 = c'_2		
	2			
1	+ 13 = c'_3.			

The transformed equation is therefore $x'^4+13x'^3+58x'^2+111x'-27=0$. If the several addends be suppressed and performed mentally, the operation will be reduced to the following:

1	+ 5	+ 4	+ 3	− 105 (2
	+ 7	+ 18	+ 39	− 27
	+ 9	+ 36	+ 111	
	+ 11	+ 58		
	+ 13			

It is on the principle of this operation that Mr. Horner has founded his general method of evolving the numerical value of a real root of an equation, which consists in similarly diminishing the equation by the successive digits of the root.

Some of the most useful properties of equations are here annexed.

1. If the real roots of an equation, ranged in the order of their magnitudes, be $r_1, r_2, r_3 \ldots$, r_1 being the greatest, r_2 the next in magnitude, &c.; and if a number a greater than r_1 be substituted for x, the result will be positive; if a number b, in magnitude between r_1 and r_2, be substituted for x, the result will be negative, &c., and so on with alternate signs.

2. No equation can have a greater number of positive roots than there are changes of sign from + to − and from − to +, in the terms or coefficients of its expression; nor can it have a greater number of negative roots than of permanencies of sign in the same terms.

3. Let p and q be any two numbers, such that q with its sign is greater than p with its sign; then, if an equation in x has m real roots comprised between p and q, the transformed equation in $(x-p)$ will have *at least m* variations more than the transformed equation in $(x-q)$.

4. For conciseness let $X=0$ denote any equation, and let the differential coefficient $\frac{dX}{dx}$ be denoted by X_1; then will the real roots of the equation $X=0$ be limits to those of the equation $X_1=0$; that is, the roots of the latter equation, taken in the order of magnitude, will fall severally *between* those of the original equation.

5. Assuming the same notation as in the last, the greatest common measure of the two expressions X, X_1, equated with *zero*, will determine the values of all *equal* roots that may be repeated in the equation $X=0$; if there be *no common measure*, the roots will be *all unequal*.

A very important theorem has been recently discovered by M. Sturm, by which we are enabled, without fail, to ascertain, by a direct process, the nature and situation of all the real roots of an equation. It is as follows: Let $X=0$ be any equation whose coefficients are real, and whose roots are unequal; and let X_1, as before, be the differential coefficient, $\frac{dX}{dx}$, of x. Let the operation of finding the greatest common measure of X and X_1 be performed; and in the several remainders which successively arise in the course of the process change all the signs from + to −, and from − to +. Suppose now that in the several resulting expressions,

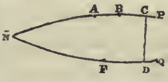
$$X,\ X_1,\ X_2,\ X_3 \ldots\ldots X_m$$

two numbers, p, q, such that $p<q$ be successively substituted for x, the results will furnish two series of signs; and, according to Sturm's theorem, the difference between the number of variations of algebraic sign in the first series and that of the second will always express *exactly* the number of real roots of the proposed equation comprised between p and q. If $-\infty$ and $+\infty$ be taken for p and q, the *total number* of real roots may thus be immediately ascertained.

For a demonstration of this remarkable theorem, see *Young's Treatise on Equations.*

EQUATION OF TIME, in Astronomy, denotes the difference, expressed in mean solar time, between the true or apparent right ascension of the sun and its mean right ascension. It may be popularly defined as the difference between the times indicated by an accurately constructed sun-dial and a well-regulated clock.

The equation of time arises from the combined operation of all the causes which tend to produce inequalities of the sun's motion in right ascension. The first of these is the eccentricity of the solar orbit, in consequence of which the sun's motion in longitude is unequal. The second is the obliquity of the ecliptic, in consequence of which the arcs of the ecliptic and equator, counting from the intersection of these circles to the meridian, are in general unequal. The third cause of the equation of time arises from the perturbations of the moon and planets, which sensibly affect the sun's motion in longitude. The different parts of the equation of time are collected and computed in the following manner: — Let N P represent the ecliptic, N Q the equator; and let N be the intersection of these circles, or the first point of Aries.



Take N A to represent the mean motion of the sun in any given time T, reckoning from the vernal equinox; then, if the sun advanced equably in the ecliptic, his place at the time T would be at the point A. But suppose that in consequence of the eccentricity of the orbit he would have advanced to B; then A B is what is called the equation of the centre. Suppose, further, that by the combined action of the planets during the time T he is carried forward to C; then the *true* arc of the ecliptic described by the sun is N C. Now, if we put

l = N C, the sun's true longitude,
m = N A, the sun's mean longitude,
e = A B, the equation of the centre,
p = B C, the effect of the perturbations,

there will result the equation $l=m+e+p$. Through C let the arc C D be drawn perpendicular to the equator; the point D will be that point of the equator which passes the meridian at the same time with the sun. If we now make r=N C−N D; then r is the *reduction to the ecliptic*, and the sun's *true* right ascension is $l-r$ = N D. Let N F = N A = m; then F is the point of the equator which the sun would occupy at the instant he occupies the point A in the ecliptic if he moved uniformly in the equator, and N F is the sun's *mean* right ascension. The mean sun would consequently pass the meridian with the point F, whereas the true sun passes it with the point D; therefore at the instant of true noon, when the points C and D are on the meridian, the mean sun is at the distance D F from the meridian. But D F = N D − N F $=l-r-m$ $=e+p-r$, which is the equation of time expressed in an arc of a circle. To convert it into mean solar time, we must multiply by 24 hours (corresponding to 360 degrees); therefore, representing the equation of time by t, we have

$$t=\tfrac{1}{15}(e+p-r).$$

This equation still requires to be corrected for the effect of nutation. The variation of the mean longitude resulting from the nutation is expressed by the formula 18″ sin. (360°− moon's node) = 18″ sin. N; and this reduced to the equator is 18″ sin. N cos. ω (ω being the obliquity of the ecliptic). Consequently the effect on the equation of time, being the difference of the variations on the ecliptic and equator, becomes 18″ sin. N (1 − cos. ω). But 18″ (1 − cos. ω) being reduced to time, becomes 0·09925 seconds; therefore, including the correction for nutation, the equation of time becomes finally

$$t=\tfrac{1}{15}(e+p-r)+\text{sin. N}\times 0{\cdot}09925 \text{ sec.}$$

The last term of this expression is very small, amounting when greatest to less than the tenth of a second, and is therefore scarcely sensible. The part depending on the perturbations is also very small, and can scarcely exceed two seconds. The principal parts, therefore, are the two depending upon the eccentricity and obliquity; and these were known in the time of Ptolemy.

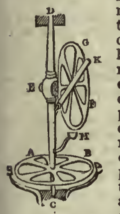
The equation of time is at its maximum about the beginning of November, when it amounts to about 16 min. 16 sec.; and is subtractive, that is to say, the clock is faster than the dial by that quantity. At four times in the year the equation vanishes, or the clock time and dial time agree. This happens about the 25th of December, the 16th of April, the 16th of June, and the 1st of September. But these epochs, depending on the longitude of the sun's perigee, are subject to some variation. The equation is given in the *Nautical Almanac* for every day of each year.

EQUATOR. In Astronomy, the great circle of the celestial sphere, of which the plane is perpendicular to the axis of the earth's diurnal motion. It is called the equator, because when the sun is in its plane the days and nights are exactly equal all over the world. The equator divides the sphere into the northern and southern hemispheres and the apparent diurnal motions of all the celes-

tial bodies are performed in circles which are parallel to it. The right ascensions are measured on the equator; and the declinations on circles which intersect it at right angles. The equator, in the heavens, is often styled the *equinoctial*.

In Geography, the equator is the great circle of the terrestrial sphere which is every where equally distant from the two poles, and divides the earth into the northern and southern hemispheres. Terrestrial *longitudes* are measured on the equator, or some one of its parallel circles; commencing from some arbitrary point, which different nations assume variously, most of them adopting the meridian which passes through their capital city or principal observatory. *Latitudes* are counted from the equator along the meridian.

EQUATO'RIAL. An astronomical instrument, contrived for the purpose of directing a telescope upon any celestial object of which the right ascension and declination are known, and of keeping the object in view for any length of time, notwithstanding the diurnal motion.



For these purposes, a principal axis C D, resting on firm supports, is placed parallel to the axis of the earth's rotation, and consequently pointing to the poles of the heavens. On this polar axis there is fixed, near one of its extremities, a graduated circle A B, the plane of which is perpendicular to the polar axis, and therefore parallel to the earth's equator. This circle is called the *equatorial* circle, and measures by its arcs the hour angles, or differences of right ascension. The polar axis is pierced at E F, and penetrated by the axis of a second circle G H, at right angles to it. The axis of the second circle has consequently no connection with any external support, but is sustained entirely by the polar axis. The plane of the second circle G H, which is called the *declination* circle, and carries the telescope K, is thus in all positions at right angles to the plane of the first or equatorial circle A B. Now it is easy to conceive, from this general description, that when the telescope is pointed to a star, the angle between the direction of the telescope and the polar axis is equal to the polar distance of the star; consequently, when a motion is given to the polar axis without altering the position of the telescope on the declination circle, the point to which the telescope is directed will always lie in the small circle of the heavens coincident with the star's diurnal path; and hence, if the motion communicated to the polar axis be just equal to the earth's diurnal rotation, the star will remain constantly, and as long as we please, in the field of the telescope, at least while above the horizon. In many observations this is indispensable, and it is an advantage which attaches to no other instrument. The polar axis may be moved by a peculiar kind of clock machinery, adjusted to sidereal time; and the best and largest equatorials are now furnished with such an apparatus. Besides relieving the observer from the fatigue of turning the instrument, the motion thus given is perfectly equable, and all those jerks avoided which, when the instrument is turned by the hand, often prove fatal to an observation. (For the method of adjusting the equatorial, see a paper by Professor Littrow of Vienna in the *Memoirs of the Royal Astr. Society*, vol. ii. p. 45.)

E'QUERRY. (Fr. ecuyer.) In the British Court, a subordinate officer under the master of the horse. The chief equerry is also styled clerk marshal, with a salary of 500*l*. per an. There are also four equerries in ordinary, whose salary is 300*l*. a year, and an equerry of the crown stable. A queen consort has three equerries.

E'QUIA'NGULAR FIGURE. (Lat. æquus and angulus.) In Geometry, a figure of which all the angles are equal among themselves, as is the case with all the regular polygons. Two figures also of the same kind, having each angle of the one equal to a corresponding angle of the other, are said to be *equiangular*, although when considered separately they may not be equiangular figures.

EQUILA'TERAL BIVALVE. A shell is so called when a transverse line drawn through the apex of the umbo bisects the valve into two equal and symmetrical parts.

EQUILA'TERAL FIGURE, in Geometry, is one that has all its sides equal to each other. Equilateral figures inscribable in circles are necessarily equiangular; but the converse does not always hold true. When the number of sides is odd, the equiangular figure inscribable in a circle is always equilateral; but when the number of sides is even, they may either be all equal, or one half equal to each other, and the other half equal to each other, though not to the former, the two sets being placed alternately.

EQUILA'TERAL HYPERBOLA, is that which has the two axes equal to each other, the asymptotes forming a right angle. See HYPERBOLA.

EQUILI'BRIUM. (Lat. æquus, *equal*, and libra, *balance*.) In Statics, results from the simultaneous action of several forces on a body, or material point, when they reciprocally destroy each other's action, so that the body or point, though free to move, remains at rest. Two equal forces, acting in contrary directions, destroy each other; and when a body submitted to the action of several forces remains at rest, it is necesary that the resultant of one part of the forces be exactly equal and opposite to the resultant of the remainder, or that the resultant of the whole be nothing. The science of equilibrium is thus founded entirely on the composition of forces. *See* STATICS.

EQUILIBRIUM. (Lat.) In the Fine Arts, the just poise or balance of a figure or other object, so that it may appear to stand firmly. Also the due equipoise of objects, lights, shadows, &c. against each other by some striking feature. This quality is obvious in the works of nature, as well in the human form as in landscape. In the latter, for instance, the sun is generally the medium of producing it by strong contrasts of light and shadow. In architecture, the same means are employed to produce the most striking effects, on the theory of which Le Roy has ably written.

EQUILIBRIUM. In Politics. *See* BALANCE OF POWER.

E'QUIMU'LTIPLES. The products of quantities multiplied by the same numbers. For example, $5\,a$ and $5\,b$ are equimultiples of a and b; and $m^2\,n\,p$ and $m^2\,n\,q$ are equimultiples of p and q. Equimultiples of quantities have to each other the same ratio as the quantities themselves.

EQUINO'CTIAL. (*See* EQUINOX.) The great circle formed by the intersection of the plane of the earth's equator with the sphere of the heavens. This term is chiefly met with in the older books of astronomy, the term *equator* being now generally given to the same circle. *See* EQUATOR.

EQUINOCTIAL POINTS. The two opposite points of the celestial sphere, in which the ecliptic and equator intersect each other; the one being the first point of Aries, and the other the first point of Libra. The equinoctial points do not retain a fixed position relatively to the stars, but retrograde or move backwards from east to west with a slow motion, equal to about 50 seconds yearly requiring 25,000 years to accomplish a complete revolution. This motion is called the precession of the equinoxes.

E'QUINOX (Lat. æquus, and nox, *night*), in Astronomy, is the time at which the sun passes through the equator in one of the equinoctial points. When the sun is in the equator the days and nights are of equal length all over the world, whence the derivation of the term. This happens twice every year; namely, about the 21st of March, and the 22d of September: the former is called the *vernal* and the latter the *autumnal* equinox. The equinoxes do not divide the year into portions of equal length; for in consequence of the sun being at his greatest distance from the earth during the summer months, and his angular motion in his orbit being consequently slower, the interval from the vernal to the autumnal equinox is greater than that from the autumnal to the vernal. In other words, the sun continues longer on the northern than on the southern side of the equator. At the beginning of the present century, the difference amounted to 7 days 16 hours and 51 minutes. The summer in the northern hemisphere is consequently longer than in the southern by this quantity; and to this circumstance some meteorologists ascribe, in part at least, the higher temperature that is found to prevail in the northern hemisphere under the same parallel of latitude.

E'QUIPAGE (Fr. equipper), in ordinary language, signifies the carriage, horses, and liveries which indicate the fortune or rank of any gentleman when he appears abroad. — *Equipage*, in marine affairs, signifies the crew of a ship, together with all a ship's furniture, masts, sails, ammunition, &c. In the art military, it denotes all sorts of utensils and artillery, &c., necessary for commencing and prosecuting with ease or success any military operation.

E'QUISETA'CEÆ. (Equisetum, one of the genera.) A natural order of Gymnosperms, inhabiting the ditches and rivers of most parts of the world. They have no decided affinity with any known order, but are more like flowering plants than flowerless; and therefore are best considered as a degeneration of *Coniferæ*, to which they have so much resemblance, rather than as a race in affinity with ferns, with which they have no resemblance. They have no medicinal qualities; but for economical purposes are useful for polishing furniture, owing to the quantity of silex contained in their epidermis. They are considered by the farmer, who calls them horsetails, as a sign of heavy, bad, wet land.

E'QUISE'TIC ACID. A peculiar acid, discovered by Braconnot existing, combined with magnesia, in the *Equisetum fluviatile*.

E'QUITANT. In Botany, a term used in describing the vernation of leaves, to denote that they overlap each other parallelly and entirely, without any involution, as the leaves of Iris. They seem as if they bestrode each other in opposite directions, whence the name.

E'QUITES. In Ancient History, a class of Roman citizens, commonly represented by the English word

knights, but not answering in all respects to its meaning. The origin of the Equites was the body of Celeres, instituted by Romulus; and they originally consisted of those who were rich enough to serve in war on horseback, but afterwards they became a distinct order. They were chosen promiscuously from the patricians and plebeians whose age was above 18 years, and fortune, at least towards the end of the republic, not less than 400 sestertia, or 3229*l*. The badges of the equites were a golden ring and a robe with a narrow purple border; and to them were appropriated the fourteen rows of seats in the theatres next the orchestra, where the senators sat. This body disputed with the senate the privilege of forming the jury who assisted the prætor in trials; but, after repeated transfers of this office from one to the other, it was finally shared between both. The equites also furnished the farmers of the public revenue, or *publicani;* but though they had enjoyed this privilege under the republic, it was only during the empire that they looked to such offices as their birthright. Cicero affirms that the flower of the Roman chivalry, the ornament of Rome, the strength of the empire, lay in these engrossers of the public revenue: "florem equitum Romanorum, ornamentum civitatis, firmamentum reipublicæ, publicanorum ordine contineri." (See *Niebuhr's Roman History.*)

E'QUITY. (Lat. æquitas.) In Jurisprudence. In the words of Blackstone (*Comm.* i. 61.), "Since in laws all cases cannot be foreseen or expressed, it is necessary that when the general decrees of the law come to be applied to particular cases, there should be somewhere a power vested of defining those circumstances which (had they been foreseen) the legislator himself would have expressed." In the same view, Grotius defines equity, as "Correctrix ejus in quo lex propter universalitatem deficit" (*De Æquitat.* i. s. 12.); and distinguishes it from the dispensing power, which does not mitigate law, but dispenses certain persons from the obligation of it. Puffendorf considers it under two heads,—as declaring a case to be excepted out of the general provisions of a law; and as deciding omitted cases on which the law does not pronounce at all. (*Elements*, i. 22, 23.) The necessity of some power to modify and apply, with allowances for particular cases, the strict rules of law, is necessarily felt in every jurisprudence, and provided for in different ways. Thus in ancient Rome the prætor, "juvare, supplere, interpretari, mitigare, jus civile potuit; mutare vel tollere non potuit." (*Digest*, l. i. t. 1. 7.) So, in English law, the judges have constantly assumed the authority to pronounce cases to be within the "equity," as it is termed, of statutes or rules, when they are not within its words; as, for example, action of waste given by the Statute of Gloucester against tenant for life "or years" is extended by equitable construction against tenants who hold for a year or half a year only. But the word equity, in English jurisprudence, is now more properly applied to a separate body of law, created and sustained on the strength of precedents, and administered by tribunals distinct from the common law courts of the country. The separation of equity from law originated in the necessity which has already been spoken of; but from the circumstance of the former being administered by a different class of functionaries, it has by degrees assumed this distinct shape and substance. By seeking relief in equity is now meant, not so much applying for a mitigation of the strict rules of law, as seeking a remedy before a tribunal having a jurisdiction either concurrent with the courts of law or (in some cases) exclusive, but exercising it according to a different process and on different principles. The origin of this peculiar system is to be traced, in part, to the system of uses (*see* USE, TRUST); in part to the obvious advantages resulting from the examination of the parties, and compelling discovery on oath in cases of fraud, account, &c.; and to the power, gradually acquired by equity judges, of compelling the specific performance of contracts where courts of law could only award damages for their breach; in part, also, to the peculiar functions imposed by statute and usage on the lord chancellor as guardian of infants, idiots, and lunatics, superintendent of charities, &c. The general view of the system of equitable jurisprudence as at present existing is given in the articles CHANCERY and TRUST. (See *Blackstone's Commentaries*, vol. iii.; *Fonblanque on Equity; Mitford's Pleadings in Chancery.*)

EQUI'VALENTS, CHEMICAL. A term introduced into chemistry by Dr. Wollaston to express the system of definite ratios in which substances reciprocally combine, referred to a common standard of unity. If we assume hydrogen as unity, it being the substance which combines with others in the smallest relative weight or proportions, then all other substances may be represented by certain multiples of that unit, expressed with sufficient precision for all ordinary purposes by whole numbers. (*See* ATOMIC THEORY and AFFINITY.) Thus, upon this system the equivalent number of oxygen will be 8, and that of water will be 9, for 8 oxygen + 1 hydrogen = 9 water; and the equivalent of potassium will be 40, and of potassa or oxide of potassium 48, for 40 potassium + 8 oxygen = 48 potassa. Upon the same principle the equivalent of hydrochloric acid, which is a compound of chlorine and hydrogen, is 37, for it consists of 1 part by weight of hydrogen and 36 of chlorine; or, in other words, of an atom of hydrogen = 1 + an atom of chlorine = 36. The equivalent of sulphur is 16: to form sulphuric acid one atom of sulphur = 16 combines with 3 atoms of oxygen $(8 \times 3) = 24$; hence the equivalent of an atom of sulphuric acid is $16 + 24 = 40$. These equivalents are often expressed by certain abbreviations, termed *chemical symbols;* which, as far as single equivalents of the simple substances are concerned, are represented, together with their equivalent numbers, in a table in the article CHEMISTRY.

E'QUIVALVE. A bivalve is so called when its two valves are of similar size and form.

EQUI'VOCAL TERM. In Logic, a term which has several significations, applying respectively and equally to several objects. A word is generally said to be employed equivocally where the middle term is used in different senses in the two premises (*see* SYLLOGISM); or where a proposition is liable to be understood in various senses, according to the various meanings of one of its terms.

EQUU'LEUS (Lat.), called also *Equiculus* and *Equus Minor*. The *Little Horse;* one of Ptolemy's constellations in the northern hemisphere.

EQUULEUS was also the name given in antiquity to a species of rack used in extorting confessions. It was originally practised on slaves, but at a later period it was employed against the Christians.

E'QUUS. (Lat. *a horse.*) The generic name of the quadrupeds with a single digit and hoof on each foot, as the *horse, ass*, and *zebra*. Of these species the horse is the largest, most docile, most valuable, and most widely distributed over the globe. Of the Mammalia which existed on the earth's surface during the tertiary periods of geology, the horse is one of the few which have been preserved to the present epoch; and in the American continent, where it once became extinct, along with the Mastodon and Megatherium, it now again ranges wild in vast troops, the descendants of the war horse introduced by the European discoverers and conquerors of the so called "new world."

The first record of the taming and application of the horse to the purposes of man is in Genesis, 19.; in which it is written, that when Joseph transferred his father's remains from Egypt to Canaan, "there went up with him both chariots and horsemen." The period when the horse is thus indicated as a beast both of draught and burden, is calculated to have been 1650 years before the birth of Christ. Horse and chariot races formed part of the Olympic games in Greece, 1450 years B. C.

The wild horses which inhabit the steppes of Tartary are supposed to be, like those that traverse the pampas of South America, descendants of certain individuals which had escaped from the thraldom of man. The best of the wild Asiatic races are those which inhabit Tscherkessi, Abassi, and the northern slopes of the Caucasian range. The principal varieties which Pallas indicates in the Asiatic horse are, first, the "moustachoed horse," characterized by numerous strong bristles on the upper lip; the "woolly horse," a Russian variety, covered with a crisp woolly hair, and common among the Baschkirs; a naked or hairless horse, not uncommon amongst the Krim Tartars, who keep it always clothed; lastly, the variety delineated by Johnston, in which a woolly mane is continued from the neck along the middle of the back to the tail, and which Pallas saw among the Buracti.

The wild horses appear to be free from nearly all those diseases to which the domestic breed are prone. They are generally of a pale or greyish brown colour, with brown mane and tail, a whitish muzzle, changing to black about the mouth. They are less than the domestic breed; with a larger head; longer legs; larger ears, with the apices sub-reflected; the forehead is more convex above the eyes; the hoofs are contracted and sub-cylindrical (*ungulæ contractæ, subcylindraceæ*); mane sub-erect, less lax than in the domestic horse; the coat, in winter, looser and sub-undulated along the back (*in dorso sub-undulatum*); the tail not very large. They recognize the presence of man at a great distance when he approaches them to windward, and fly from him with wonderful speed; they prefer sunny slopes, and avoid forests and steep places. They do not wander beyond the 50th degree of north latitude. Wild stallions attracted by domestic mares are often taken and killed.

The first change which domestication works upon the form of the wild horse is to increase the bulk of his trunk as compared with his head and limbs. This change is beautifully exemplified in the Arabian, which we must regard as an early, if not first remove, from his wild neighbours of the more northern deserts, and which the Bedouin still hunts for the sake of their flesh. The head is not only proportionally smaller, but is remarkable for the breadth and squareness of the forehead, the shortness and fineness of the muzzle, the prominence and brilliance of the eye, and the smallness of the ears. The body is still somewhat light, and narrow at the forepart;

but the shoulder is superior in its formation to that in any other breed. The Arabian seldom stands more than 14 hands 2 inches. The "Barb," so called from its native country, Barbary, is somewhat smaller than its near ally the Arabian; it seldom exceeds fourteen hands and an inch; the shoulders are flat, the chest round, the legs rather long, and the head small and very beautiful. The Barb is remarkable for its fine and graceful action; but though it is superior to the Arabian in its general form, it has not its untiring spirit or its speed. Our most valuable English varieties of the horse date from the introduction of, and interbreeding with, the Barb and Arabian.

We have no means of ascertaining the nature or peculiarities of the horses which the ancient British charioteers managed with such dexterity in their destructive charges through the disciplined troops of Cæsar. They must have been subsequently modified by crossing with the Roman horses. King Athelstan received from Hugh Capet of France several German running horses; William the Conqueror and his followers introduced the Spanish horse, with the blood of the Barb. The first Arabian horse is recorded to have been introduced in the reign of Henry I.; and a greater admixture of Arabian blood was a natural consequence of the return of the Crusaders. King John devoted especial attention to the improvement of his stud; and he imported one hundred choice stallions of the Flanders kind. The size and strength required to carry the warrior clad in the heavy armour of those days led to the frequent introduction in subsequent reigns of the large and heavy war horses of the Low Countries. Afterwards, when the nobles derived their amusements more from the sports of the turf and field, they were induced to cross their stately and heavy breed of war horses with those of lighter structure and greater speed; the latest improvement seems to have been derived from a direct intermixture of the pure Arabian.

The principal varieties or breeds of English horses are — The hackney or road horse. "He should be," Mr. Youatt observes, "a hunter in miniature; with these exceptions: His height should rarely exceed fifteen hands and an inch. He will be sufficiently strong and more pleasant for general work below that standard. He should be of a more compact form than the hunter, of more bulk according to his height. It is of essential consequence that the bones beneath the knee should be deep and flat, and the tendon not *tied in*. The pastern should be short, and less oblique or slanting than that of the hunter or race horse. The foot should be of a size corresponding with the bulk of the animal, neither too hollow nor too flat, and open at the heels. The forelegs should be perfectly straight; for a horse with his knees bent will from a slight cause, and especially if overweighted, come down. The back should be straight and short, yet sufficiently long to leave comfortable room for the saddle between the shoulders and the *huck* without pressing on either. Some persons prefer a hollow-backed horse. It is generally an easy one to go. It will canter well with a lady; but it will not carry a heavy weight, or stand much hard work. The road horse should be high in the forehead, round in the barrel, and deep in the chest."

The origin of the better kind of *coach horse*, says Mr. Youatt, is the "Cleveland bay," confined principally to Yorkshire and Durham, with Lincolnshire on one side and Northumberland on the other, but difficult to meet with pure in either county. The Cleveland mare is crossed by a three-fourth or thorough-bred horse of sufficient substance and height, and the produce is the coach horse most in repute, with his arched crest and high action.

There is, or rather was, a breed called, from its round punchy make, the *Suffolk punch*. "It stood from fifteen to sixteen hands high, of a sorrel colour; was large-headed, low-shouldered, and thick on the top; deep and round-chested; long-backed; high in the croup; large and strong in the quarters; full in the flanks; round in the legs, and short in the pasterns. It was the very horse to throw his whole weight into a collar, with sufficient activity to do it effectually, and hardihood to stand a long day's work." This valuable breed is now nearly extinct: it is thought to have been produced from the Norman stallion and the Suffolk cart mare. Excellent carriage horses are obtained by crossing the Suffolk breed with a good hunter.

The best dray horses are produced from the Suffolk punch crossed with the Flanders.

The breed of English racers is traced authentically to an Arabian stallion introduced into this country by a Mr. Darley, and hence called the "Darley Arabian." Anterior to this period the pedigree of a racer can rarely be carried back beyond some obscure reference to an Eastern horse. The Darley Arabian was the sire of Flying Childers, and the great grandsire of Eclipse. Eclipse was remarkable for the very great size, obliquity, and lowness of his shoulders; the shortness of his forequarters; his ample and finely proportioned quarters, and the swelling muscles of his fore-arm and thigh. He was, moreover, what is termed a thick-winded horse, and puffed and roared so as to be heard at a considerable distance; yet he never had an opponent on the turf sufficiently fleet to put his full speed to the test. Eclipse died at the age of twenty-five years, having begot the extraordinary number of three hundred and thirty-four winners.

Another stream of Eastern blood was introduced into the swelling veins of our thorough-bred horses by a beautiful Barb, called the Godolphin Arabian.

The hunter, a favourite English variety, includes as much of the blood and high breeding of the racer as is compatible with the power and endurance demanded by the chase. The author of the excellent work on the horse in the *Library of Useful Knowledge*, thus describes the good points of a hunter: — "The first property of a good hunter is, that he should be light in hand. For this purpose his head must be small; his neck thin, especially beneath; his crest firm and arched; and his jaws wide. The head will then be well set on. It will form a pleasant angle with the neck, which gives a light and pleasant mouth."

The more extreme varieties which we have in England are the ponies and Galloways: of these the Sheltie or Shetland pony is the most diminutive; it rarely exceeds nine hands high, and sometimes does not reach seven and a half. His strength is proportionally far greater than his size; he is perfectly docile, and will fatten on the hardest fare.

The dental character of the horse, and of the genus *Equus*, is thus expressed in zoology: —

Incisors $\frac{6}{6}$, Canines $\frac{1 \cdot 1}{1 \cdot 1}$, Molares $\frac{6 \cdot 6}{6 \cdot 6} = 40$; *i. e.* it has six incisors or nippers in the front of both the upper and lower jaws, one tusk or canine, and six molars or grinders, on each side of both jaws. They appear in the following order: — The two middle incisors, and the two anterior grinders, come into place at about a week after birth; the third grinder in the course of the first month; the two adjoining incisors before the end of the sixth week; the two outer incisors between the sixth and ninth month; making the six incisors above and below, and completing what is termed the colt's mouth. There are also two very small deciduous canines developed about the sixth month; the fourth grinder generally makes its appearance at the end of the first year; and thus the formula, incisors $\frac{6}{6}$, molares $\frac{4 \cdot 4}{4 \cdot 4}$, is characteristic of the yearling foal. A fifth grinder makes its appearance at the end of the second year; and now commences the displacement of the first set, and the protrusion of the second or permanent set of teeth. The deciduous teeth are lost in the order of their acquisition; the two middle incisors of both the upper and lower jaws are displaced *between the second and third years;* the first and second deciduous grinders are shed at two years and eight months. A *three-year old* colt has the permanent middle incisors above the gum, but not on a level with the adjoining deciduous incisors; they are also characterized by a large and deep groove containing a black substance traversing transversely the working edge of the crown of the tooth; the *sixth grinder is also coming into place.* At *three years and a half* or little later the adjoining deciduous incisors are shed, and their large successors begin to peep above the gum; the small lateral incisors are diminished in size and much worn. This gives a very characteristic condition to the mouth.

At *four years* the sixth grinder has attained the level of the others; the permanent tusks begin to appear; the second permanent incisors have come into place, and are marked with a deep fissure extending quite across the edge of the crown; the corresponding mark in the middle incisors is worn wider and fainter; the third deciduous grinder is shed. The external incisors are shed *between four and a half and five years.* At *five years* their permanent successors are in place, with a long deep mark on the inner side of the edge of the crown. The corresponding mark is much worn in the middle incisors, and to a less degree in the adjoining ones. The tusks are about an inch in length. At *six years* the mark or fissure on the middle incisors is worn away, but a discolouration on the part remains; the mark in the adjoining incisors is shorter, broader, and fainter; and the lateral incisors present the edges of the enamel in a more regular state, and evidently worn; the tusks are an inch in length and pointed; the third permanent grinder has taken its place in the dental series. At *seven years* the mark is worn away on the four middle incisors in both jaws, and in progress of obliteration in the lateral incisor: the apex of the canine or tusk is blunted. At *eight years* the mark is gone from all the lower incisors, and they cease to afford any indication of the subsequent age of the horse. The tusks are rounded off; the marks remain longer on the incisors of the upper jaw. Of course the marks are obliterated in proportion to the friction to which

the teeth are subject; they are sooner lost in a stall-fed horse than in one at grass; they are prematurely worn away in the crib-biter.

The age of a horse being always calculated from the 1st of May, it is very difficult to determine whether an animal be a late foal of one year or an early one of the next. A horse may be made to appear older than he really is by premature extraction of the deciduous teeth; or younger by imitating artificially the natural marks of the incisors after they have been obliterated by attrition; but these frauds are readily detected when all the concomitant conditions of a horse's mouth are scanned by the practised eye.

Owing to the premature labour to which the horse is in general condemned in this country, and to the present rapid rate of travelling, he has rarely a chance of living out his natural term of existence. A well-used horse may last between thirty and forty years. Mr. Percival gives an account of a barge-horse that died in his sixty-second year. Mr. Youatt quotes the record of another horse that received a ball in his neck at the battle of Preston in 1715, and which was extracted at his death in 1758.

ERA. *See* Æra.

ERA'SED, in Heraldry, signifies any thing forcibly torn off, leaving the edges jagged and uneven; as, a lion's head erased, &c.

ERA'STIANS. The followers of Erastus, a German divine; a sect which obtained some notoriety in England in the time of the civil wars. They referred the punishment of all offences, civil or religious, to the civil magistrate; and asserted that the church had no power to enforce any acts of discipline, nor to refuse the communion of the Lord's Supper to any one who desired it.

E'RATO. (Gr. ερως, *love.*) In Ancient Mythology, the muse who presided over love poetry. (See *Callimachi Epigramm.*) She is frequently confounded with Terpsichore; and in the 7th Book of the *Æneid* she is invoked by Virgil as synonymous with Calliope.

E'REBUS. (Gr. Ερεβος.) According to the classic mythology, the son of Chaos and Darkness, who dwelt in the lowest part of hell, which is frequently called by his name.

ERETHI'SMUS. (Gr. ερεθιζειν, *to excite.*) This term is generally applied to a peculiarly irritable state of constitution, which occasionally results from the use of mercury, and in which there is great depression of strength and irregularity of pulse, anxiety, paleness, and tremors.

E'RGOT, or CLAVUS, is a disease of the rye, produced by the attack of fungi which take possession of the ovary and destroy it, producing in its room a long, black, hard, hornlike body. It is remarkable for the specific stimulating effects it produces upon the uterus, on which account it is much employed in cases of difficult parturition.

ERICA'CEÆ. (Erica, one of the genera.) A natural order of shrubby Exogens, inhabiting the Cape of Good Hope and many other places. It differs from *Vaccinaceæ* and *Campanulaceæ* in the superior ovary; from *Epacridaceæ* in the anther being two-celled; from *Pyrolaceæ* and *Monotropaceæ* in the structure of the seeds, and in habit; and from all the orders represented by *Scrophulariaceæ* and *Gentianaceæ* in the number of the cells of the ovary agreeing with the lobes of the calyx and corolla. Their general qualities are astringent and diuretic, some few being poisonous. The *Arbutus*, *Andromeda*, *Kalmia*, *Rhododendron*, *Azalea*, all well known shrubby plants of great beauty, belong to this order.

ERI'CHTHIANS. *See* Erichthus.

ERI'CHTHUS. (Gr. ηρι, *early*, and χθων, *the earth.*) A genus of long-tailed Decapod Crustaceans, inhabiting the tropical ocean. These crustacea are remarkable for the delicate and often transparent and colourless character of their large and undivided thoracic shield or carapace, which always is terminated anteriorly in a styliform rostrum: they have no moveable rostral plate, and the gills are in general very small and simple, and sometimes wholly inconspicuous. The genus thus characterized is now subdivided into *Squillerichthus*, *Almia*, and *Erichthus* proper; and the whole are included under the family name of *Erichthians*, or *Erichthidæ*, which in the natural system ranks next to the *Squillidæ*, or sea mantises.

ERI'DANUS. (The river Eridanus.) One of the ancient constellations in the southern hemisphere, first mentioned by Aratus.

ERINA'CEUS. (Lat. erinaceus, *a hedgehog.*) A genus of useful insectivorous Mammals, of which our common hedgehog is a well-known and unmeritedly persecuted species. The teeth are small, and form a series of sharp bristling points, well adapted for the crushing of beetles, or cracking the back-bone of a snake; but quite inadequate to the purpose of self-defence against larger carnivorous quadrupeds. Nature has, however, provided the hedgehog with a compensatory coat of armour, thickly bristled over with strong elastic spines, and capable of being drawn by powerful cutaneous muscles over every part of the body. When the hedgehog thus puts himself in a defensive attitude, he resembles a bristled sphere; and is capable of enduring hard blows or heavy falls without suffering material injury.

Mr. Bell says, in his excellent history of British quadrupeds, "The strength and elasticity of this covering is such, that I have repeatedly seen a domesticated hedgehog in my own possession run towards the precipitous wall of an area, and without hesitation throw itself off; and contracting at the same instant into a ball, in which condition it reached the ground from a height of twelve to fourteen feet, after a few moments it would unfold itself and run off unhurt."

As the food of the hedgehog consists almost entirely of cold-blooded animals, which in our climate almost entirely disappear from the scene of nature in the winter season, the hedgehog must have starved if he had not been endowed with the singular property of subsiding into a state of suspended animation during the period of famine. In order, however, to preserve the low temperature which he then possesses, he prepares in some retired hole a soft nest of moss and leaves; and thus passes his winter "undisturbed by the violence of the tempest, and only rendered still more profoundly torpid by the bitterest frost." All the store of nutriment which he carries with him to his place of hybernation is a thick layer of fat about his viscera and beneath his skin, which is slowly absorbed, as the little waste of his inactive life requires, and more rapidly during the first few days of his resuscitation in spring. The female produces from two to four young ones in the summer; they are blind, and covered with soft and flexible spines. The hedgehog has thirty-six teeth. The intermaxillary bones contain six teeth, of which the two anterior are longer than the rest, placed wide apart, directed obliquely downwards with a slight convergence. The six upper incisors are opposed to six below, of which the two anterior ones have the same disproportionate size as the corresponding ones above. Of the remaining teeth the four posterior ones on each side of both jaws are large, multicuspidate, true molares. The intermediate teeth are small, with two fangs, and represent the spurious molares.

E'RIOCAULO'NEÆ. (Eriocaulon, one of the genera.) A natural order of Endogens, inhabiting the marshes of most parts of the world: usually combined with *Restiaceæ*. It is composed of herbaceous plants, with their flowers growing in close heads, and contains no species of any known use.

ERIO'METER. (Gr. εριον, *wool*, and μετρον, *a measure.*) An optical instrument proposed by the late Dr. Young for measuring the diameters of minute particles and fibres, by ascertaining the diameter of any one of the series of coloured rings they produce. "The eriometer is formed of a piece of card or a plate of brass, having an aperture of about a fiftieth of an inch in diameter in the centre of a circle about half an inch in diameter, and perforated with about eight small holes. The fibres or particles to be measured are fixed in a slider; and the eriometer being placed before a strong light, and the eye assisted by a lens applied behind the small hole, the rings of colours will be seen. The slider must then be drawn out or pushed till the limit of the first red and green ring (the one selected by Dr. Young) coincides with the circle of perforations, and the index will then show on the scale the size of the particles or fibres." (*Brewster's Optics*, *Cabinet Cyclopædia.*)

ERI'PHIA. (Gr. εριφος.) A genus of short-tailed or Brachyurous Crustaceans, including the *Cancer spinifrons*, Herbst.; *Cancer conagra*, Fabr.; and other later discovered species.

ER'MINE. ("This," says Gwillim, "is a little beast less than a squirrel, that hath his being in the woods of the land of *Armenia*, whereof he taketh his name.") In Zoology, a species of *Mustela*, or stoat, differing from the common weasel in being about one third larger, and in having a somewhat broader head and a longer tail. In the summer season the upper part of the head, neck, and body, and the greater part of the tail, are of a pale reddish brown colour; the under parts white, with a very slight tinge of yellow; tip of the tail black, and somewhat bushy. In the winter the whole of the body becomes white, slightly tinged with yellow; but the black termination of the tail is permanent. The fur is closer and finer at this season, especially in the colder latitudes, from which countries the ermine affords one of the most beautiful and valuable of furs. When made up the tails are inserted one to each skin, at regular distances, and in the quincunx order; and thus arranged the ermine fur forms the distinctive doubling of the state robes of sovereigns and nobles, as well as of their crowns and coronets.

Ermine. In Heraldry, one of the furs used in blazonry. It represents the skin of that animal white, spotted or timbered with black. *Ermines* is black, spotted or timbered with white. *Erminites* differs from ermine in having the side hairs of the timberings red. *Erminois* is the same as ermine, except that gold is substituted for the white. *Pean* is black, timbered with gold.

ERO'DED. (Lat. erodo, *I gnaw.*) In Zoology, when

a part has its edges irregularly jagged, as if gnawed or eaten.

ERO'TIC (Gr. ἐρως, *love*), is an epithet applied generally to all that relates to the passion of love. Thus whatever excites that passion, or depicts its effects, is termed *erotic*. In a more confined sense, this appellation has been conferred on a certain class of Greek and Latin authors, both in prose and poetry, of whose writings love formed the principal theme. Of these the most distinguished are Achilles Tatius, Heliodorus, Anacreon, Sappho, Ovid, Tibullus, Propertius, &c. (See the learned work entitled *Scriptores Erotici Græci, cura Mitscherlichii.*)

E O'TOMA'NIA. (Gr. ἐρως, and μανια, *madness.*) Mental aberration, supposed to be occasioned by the passion of love.

ERPETO'LOGY, more properly *Herpetology*. (Gr. ἑρπετος, *a reptile*, and λογος, *a discourse.*) The branch of zoological science which specially treats of the class *Reptilia*. This class of animals is characterized by having a heart so constructed as to transmit to the lungs a part only of the circulating mass of blood which it receives from the systemi veins, the remainder being sent again to the body without having been purified in the lungs. There thus results a less amount of reaction of oxygen upon the blood than takes place in Mammalia, and consequently a lower grade of animal heat, and an inferior activity of muscular contraction; but, as the proportion of venous blood transmitted by the heart to the general system varies in different reptiles with the various modifications of the heart, there is a corresponding difference in the manifestation of their vital phenomena.

As reptiles are thus exempt from the office of preserving the temperature of a circulating fluid many degrees warmer than that of the external atmosphere, they have no need of teguments adapted to retain heat; and are accordingly naked, or covered with scales or hard bony plates. Their brain is very small, and without the great commissures. The lungs serve more or less as reservoirs as well as decomposers of the atmospheric air; and thus with a certain degree of independence of the general circulation, the reptiles are enabled to remain much longer under water than either birds or mammalia. Some species, indeed, have in addition to their lungs gills for breathing water, either during their immature state, or throughout life, and thus are truly amphibious. With a cold blood, low respiration, low sensation, and sluggish habits, is associated an extraordinary power of endurance of abstinence and bodily injury.

Reptiles are either oviparous, or ovoviviparous: they do not incubate. They present a great variety of forms, and constitute altogether a much less natural group than either birds or mammals. The character which Cuvier has assigned to the *Reptilia* would not seem to distinguish them from certain fishes with highly developed air bladders, without the additional statement that the organ of smell in the class *Reptilia* is situated in a canal communicating both with the cavity of the mouth and the external surface.

Cuvier divides, after Brongniart, the reptiles into four orders, viz.: —

The *Chelonia* (tortoises and turtles); of which the heart has two auricles, and the body is supported on four legs, and inclosed between two plates or shields formed by the ribs and sternum.

The *Sauria* (lizards and crocodiles); of which the heart has two auricles, and the body, supported on four legs, is covered with scales.

The *Ophidia* (slow-worms and serpents); of which the heart has two auricles, and the body is without legs.

The *Batrachia* (frogs, toads, newts, &c.); of which the heart has but one auricle, and the body is naked, and supported on four, or in a few cases two legs. Most of these pass, as they advance to maturity, from the condition of a fish breathing by gills to that of a quadruped breathing by lungs. Some, however, never lose their gills.

Such are the characters assigned by Cuvier (in 1829) to his primary divisions of the class *Reptilia*, but they are not a true expression of the organization of the groups so distinguished. The *Batrachia*, for example, have since been proved to have two auricles, although not so distinct externally as the other reptiles. Some of Cuvier's *Sauria*, again, have two distinct ventricles; whilst the rest have but one, like the *Chelonia* and *Ophidia*. The crocodiles, alligators, and gharrials are the higher organized *Sauria* here alluded to; and since they differ also from the *Lacertine Sauria* in having a simple undivided tongue and intromittent organ, and a well-marked modification of the tegumentary system, they deserve to rank as a distinct order, at the head of the class *Reptilia*. This order has been termed by Merrem *Loricata;* for the skin, in fact, instead of being covered by imbricated scales, is strengthened and protected by several rows of flattened and generally elliptical bones, developed between the cuticle and true skin, and often supporting a longitudinal crest; these bones or scutæ are situated chiefly along the back part of the neck, body, and tail.

Another order of *Reptilia* is clearly indicated by the remains of several large or even gigantic species now extinct, in which the extremities were modified to serve as fins on the plan of the paddles of the *Cetacea*. These reptiles are chiefly referable to the genera *Ichthyosaurus* and *Plesiosaurus;* they were marine, and of predaceous habits, and constitute the order *Enaliosauria*.

The *Chelonia* form a third and very natural order.

Those *Saurians* of Cuvier which have a heart composed of a single ventricle and two auricles, which have a bifid tongue and double intromittent organ, and which have a scaly and generally imbricated covering, form a fourth order of reptiles, to which the term *Squamata* has been given.

The *Ophidia* of Cuvier constitute the fifth order of reptiles. Some naturalists have proposed to unite the serpents with the lizards in the same order, on account of the gradual transition traceable in different genera from one to the other group; but the class of reptiles, by parity of reasoning, ought to be merged in that of fishes; and the naturalists who favour the blending of the tetrapodal with the apodal reptiles seem to forget that an order is a conventional division, a group of convenience, and not an entity circumscribed by nature. To separate the *Batrachia* as a distinct class from the *Reptilia*, seems to be an error in the opposite extreme. The viviparous four-footed salamander, breathing air by membranous lungs, and circulating blood by a biauricular heart, is thus placed in a distinct class from the four-footed lizard, without any essential difference in the pulmonary or sanguiferous systems to warrant the separation; the only differences that can be urged for such a step are a modification of the tegumentary covering, and a greater development and later continuance of the temporary branchial apparatus, of which traces are met with in the embryos of all the air-breathing Vertebrata; and a modification of the reproductive system. The naked integument; the presence of external gills in the young state; the almost simultaneous fecundation, sometimes without intromission, of numerous ova, — may be grounds for regarding the *Batrachia* or *Amphibia* as a subclass, or a group somewhat higher than an order; but seem not to warrant their separation from the scaled reptiles as a distinct class, as a group equivalent among Vertebrata to that of birds or mammals. For the subdivisions of the above orders see LORICATA, ENALIOSAURIA, CHELONIA, SQUAMATA, OPHIDIA, BATRACHIA, and also AMPHIBIA.

E'RPETON. *See* HERPETON.

ERRA'TA. (Lat.) The term applied to the faults that have escaped in the impression, or, as the case may be, in the composition of a work; usually inserted in a list either at the commencement or the end of the book. This manner of indicating typographical errors is coeval with the art of printing itself. Various dissertations have been devoted to this subject; among others may be mentioned that of Lindenberg, *De Erroribus Typographicis*, which, although of a somewhat impracticable nature, contains many ingenious observations.

E'RROR. In Law, a writ of error is one which authorizes the judges of a superior court to examine a record on which judgment has been given in an inferior court on an allegation of error in pleading a process, &c., and to affirm or reverse the same. It is the common remedy for erroneous judgments in courts of record. Error lies from inferior courts of record, and from the Common Pleas, to the King's Bench; from each of the three superior courts to the judges of the other two sitting in the Exchequer Chamber; from the Exchequer Chamber, and in certain cases directly, to the House of Lords. It lies in criminal as well as civil cases. Writ of error must be brought within twenty years. Correctly speaking, it is applicable only for the reversal of judgments on account of errors in law, and not of fact.

ERSE. The name given by the English and Scots to the dialect of Celtic spoken by the inhabitants of the Highlands of Scotland. The term is evidently another form of the word Irish. The people speaking the Erse tongue call themselves *Gael* (written, but not pronounced, *Gaidheal*), and their language *Gaelig*. The inhabitants of the low country of Scotland, it is remarkable enough, they call *Gall*, a term which they occasionally apply also to any stranger. England in the Erse language is called *Sasson*, meaning Saxony, and the people and language *Sassonach;* the latter being often called *Beurla*, which means speech in general, and in this case "the language" *par excellence*. The Irish are called by the Scots Highlanders *Gael*, like themselves, with the distinction of belonging to Erin, or Ireland. For the Welsh and their country there appear to be no names known to the Erse language. The Erse or Gaelic has been asserted to be one of the dialects of that Celtic or Gaulish language which is once supposed to have pervaded nearly the whole western portion of Europe, including France, Spain, and Britain. For such an hypothesis, however, there is no good evidence; and all analogy is wholly opposed to the supposition that a people so rude, so divided, and so scattered as the inhabitants of Europe were 2000 years ago, should

have had a common language. The great probability, on the contrary, is that in such times there were in Europe, as there are now in America, in Hindostan, and in the great group of the Oriental Archipelago, *many* languages; a few so closely connected as to amount only to dialects of each other, but the greater number either differing wholly, or agreeing only in a few words, — communicated possibly through the medium of religion, or adopted for convenience by the rest from one tribe or nation, which through good fortune or favourable position had obtained the start in civilization. The languages supposed to be of the Celtic stock, and of which we have sufficient evidence either by remains or as living tongues, are the Welsh, the Bas Breton or Armorican, the Irish, the Erse or Gaelic, the Manks or language of the Isle of Man, the Cornish, and the Basque or language of the provinces of the same name in Spain. An examination of these appears to prove the truth of the theory we have now suggested. The Welsh and Armorican are but dialects of the same language, and the same observation holds true of the Irish and Erse. These languages agree respectively with each other, not only in grammatical structure, but in that numerous class of words which constitutes the groundwork of every language; viz. prepositions, adverbs, conjunctions, with such verbs, adjectives, and nouns as are of most frequent and familiar use. The Irish and Erse so nearly resemble each other, that after a short familiarity with the pronunciation, the Irish and Scots Highlanders have no difficulty in understanding each other; and the same is said to be the case with the Welsh and Bas Breton. On the other hand, the languages of the two latter are wholly unintelligible to the first, and *vice versa*. The Manks is but a dialect of the Irish or Erse, and the now extinct Cornish was unquestionably a dialect of the Welsh. As to the Basque, long supposed to be a Celtic tongue, a careful examination of it by the late Baron William Humboldt showed not only that it bore no resemblance to the Welsh, the Irish, or their dialects, but that it had nothing in common with any known language, ancient or modern.

Respecting the causes which produced a similarity between the languages of Wales and Britany we possess some historical evidence. In the fourth and fifth centuries the Welsh, or people speaking the Welsh language in Britain, emigrated in great numbers to the opposite shore of the Continent, driven from their own country by the tribes of the northern part of the island. Their number was so considerable that they acquired a superiority over the native population of the part of Gaul where they settled, and succeeded ultimately in imposing on it their own name and language. A similar emigration from Ireland, although we have no historical record of it, probably propagated the name and language of the Irish, with their manners, customs, and traditions, over the poor and mountainous portion of Scotland which is now the site of the Gaelic or Erse language. It does not necessarily follow, in this case, that the Highlands of Scotland were without inhabitants when the Irish colonists or conquerors planted themselves there. A primitive race of inhabitants no doubt previously existed, whose name and language were lost in the strength and multitude of the invaders that occupied their country, as happened in America as the result of a British invasion, and in Britain itself as the result of a Saxon one. It may perhaps be said, in this instance, that the emigration is as likely to have taken place from the Highlands of Scotland to Ireland, as from Ireland to the Highlands; but the answer to such a supposition is obvious, viz. that conquest is more likely to have proceeded from an extensive and fertile country to a poor one destitute of resources, than from the latter to the former.

Although we have stated that between the Irish and Gaelic on one hand, and the Welsh and Armorican on the other, there is no such connection as would imply an identity of origin, there is still much evidence exhibiting an early and frequent communication, and probably to some extent even an intermixture of races, originating in an unsettled and stirring period of the history of the inhabitants of Europe; in such a state of society, in short, as produced within the memory and knowledge of history the migrations and invasions of the Gauls, and of the Cimbri and Teutones. The similarity of language to which we now allude bears no inconsiderable resemblance to that which is ascertained to exist between most of the languages of the great Oriental Archipelago and Pacific Ocean, and which has been satisfactorily traced from Madagascar to Gaster Island. We may take as an example the numerals, which, with few exceptions, are the same in the Irish, Erse, Welsh, and Armorican, just as they are in many, although not in all, the languages of the innumerable nations and tribes occupying the scattered islands which lie between Asia and Australia north and south, Africa, and America west and east. But the numerals, it should be recollected, are not essential and indispensable portions of rude language; but, on the contrary, as much comparatively recent inventions as an alphabet, or the Arabian system of notation; and indeed an invention, particularly when carried to the length to which it has been in this case, implying a very considerable advancement in early society. The system is, as usual, decimal; and although it contains evidence of rude attempts at local and less perfect plans, is obviously of single origin. It reckons by ten up to twenty, and then counts by scores up to a hundred. Thus nineteen is "one and nine," and expressed by the very same words in all the languages. The word for twenty in the two classes of languages differs. Thirty is expressed by the circumlocution of "one score and ten," forty by "two scores," and fifty by "two score and ten," &c. One hundred is expressed by the same term in all the languages; and it is the utmost limit of native enumeration, for a thousand and the numbers above it are borrowed from the Latin. In the example of the numerals, then, we discover, what might be looked for, evidence of considerable simplicity and even rudeness in these Celtic languages.

Of the four languages now spoken of, the Welsh appears to be that which was longest and most cultivated. It was unquestionably a written language in the 10th century; and the perfect alphabet, by which every sound in it is invariably expressed, consisting of sixteen radical and twenty-seven derivative characters, forming in all forty-three letters, is still preserved. The Erse or Gaelic was the least cultivated; and until late years even the Bible which was used in the Highland churches was no other than the Irish. It first attracted notice after the publication in the English language of the poems of Ossian, said to be derived from it about the middle of the last century. These, it was pretended, were translated from manuscripts in the translator's possession; but such poems in a written form, it is now sufficiently known, never had any existence, either in the Irish or Gaelic language. Although not committed to writing, or rather not handed down in writing, these poems, committed to memory and handed down from one bard or story-teller to another, still exist in the Highlands of Scotland, and in a dress not remote from that in which they were rendered by Macpherson into English. Their scene is sometimes laid in Scotland, but more frequently in Ireland. In short, they are the Iliad and Odyssey of the Celtic race of the two islands, handed down by tradition only,— what the poems of Homer were in all likelihood to the Greeks themselves, before the art of writing was known to them. The Erse, although a rude and uncultivated language, is a nervous and manly one, both as to expression and sound, and well suited to poetry, whether sublime or tender. The range of its sounds is very great; for it possesses twelve vowels, and no less than eighteen diphthongs and triphthongs, with forty-one consonants, including aspirates. Many of the consonants are guttural; and of these, as well as of the vocalic sounds, there are several utterly unpronounceable by a stranger: the attempts made to express such a variety of sounds by the Roman alphabet are, of course, both awkward and imperfect. As to the grammar, that of the Gaelic is of complex structure, implying a primitive language which has undergone little change by admixture with other tongues.

ERYSI'PELAS. (According to etymologists, from the Gr. *ερυεσθαι*, *to spread*, and *πελας*, *near*—spreading over the neighbouring parts; but the derivation is doubtful.) Called also *Saint Anthony's Fire*, that saint having miraculously cured it. This disease usually commences with fever, followed by an eruption of a very red colour, sometimes vesicular, and attended by tumefaction. It commonly attacks the head and face, and is at its height from the third to the sixth day; but its duration and progress are very variable in different individuals. The fever which attends this form of erysipelas is more or less inflammatory, and at first cooling diet and aperients are required; and the local irritation and itching may be quelled by cooling lotions, or by sprinkling the part with a puff of hair powder, which is sometimes singularly soothing to the sufferer. From the eighth to the twelfth day, the eruption scabs or scales off. If sickness, shiverings, and delirium attend the height of the disorder, an unfavourable termination may be anticipated. Sometimes suppuration occurs, especially of the eyelids and scalp. The greater number of cases of this disorder have a tendency, in their latter stages, to debility; and bark, or sulphate of quinine, with other tonics, are indicated. But where inflammatory symptoms run high, aperients and diaphoretics must be persevered in; and blistering, and even cupping, are necessary.

Where erysipelas is attended with typhoid symptoms, it is dangerous from the beginning; and wine, bark, ammonia, and other stimulants, are usually prescribed.

In that form of erysipelas which attacks different parts of the body in successive patches aperients, diaphoretics, and alteratives are useful; but in every case of this disease, lotions and ointments should be used with the utmost caution, and warm or cold water, and milk and water, are generally the best applications. There is a variety of erysipelas which attacks infants, and which is sometimes alarming from its gangrenous or suppurative tendency. Erysipelatous inflammation is also often a sequel of surgical operations, especially in crowded and ill-

ventilated hospitals, where it sometimes spreads among the patients to a very alarming extent. Cleanliness, ventilation, fumigation, and, above all, the removal of the affected persons to a better air, are the only chances of eradication.

ERYTHE'MA. (Gr. ερυθρος, *red.*) All *rashes*, as they are commonly called, and rednesses of the skin, attended by marked constitutional affection, and very mild forms of *erysipelas*, come under this denomination.

ERY'THRIC ACID, applied by Brugnatelli to a *red* substance obtained by the action of nitric on uric acid.

ERY'THROGEN. A peculiar substance, discovered in 1821, by M. Bizio of Venice, in the gall-bladder of a person who died of jaundice. It was a green tasteless liquid, which became *deep purple* in nitric acid and ammonia, and when heated in the air produced a purple vapour; hence its name, from ερυθρος, *red.* He supposes it identical with the colouring matter of the blood.

ERYTHRO'NIUM. A name originally given to the metal since called *Vanadium*, from the *red* colour of its acid.

E'RYX. (Gr.) A genus of serpents with a short obtuse tail and a single series of subcaudal scutæ, as in Boa; but having both the abdominal and caudal scutæ much narrower, and the anal hooks inconspicuous.

E'SCALADE. (Fr.) The scaling of a fortification by means of a ladder is so called.

ESCAPA'DE. (Fr.) A term almost naturalized in England, signifying any impropriety of speech or behaviour of which an individual is unconscious.

ESCA'PEMENT, in Clock and Watch-work, is the name given to that part of the mechanism by which the circulating motion of the wheels is converted into a vibratory motion, as that of the pendulum of a clock or balance of a watch. Various contrivances are employed for this purpose, depending on different mechanical principles, as the *dead-beat* escapement, the *lever* escapement, the *duplex* escapement, the *detached* escapement, &c. *See* HOROLOGY.

ESCA'RP (Germ. scharf, *sharp*), in Fortification, signifies any thing high and precipitous. Sometimes it is used to denote the side of the ditch next the place; in which case it is opposed to *counterscarp*, which denotes the side next the country. In a fortress, the escarp is the exterior surface of the revetment wall supporting the rampart.

ESCA'RPMENT. In Geology, the steep face often presented by the abrupt termination of strata where subjacent beds "crop out" from under them. The two most extensive lines of hill which traverse the centre and south of England are formed by the escarpments of the oolite and chalk formations respectively. The first extends through Yorkshire, the West of Lincolnshire, Rutland, Northampton, Warwick, Gloucester, Somerset, Dorset; being bounded throughout on the N. W. by the outcrop of the *lias* formation. The latter commences in Yorkshire, rises again in Norfolk, and extends through Cambridge, Hertford, Bucks, Oxford, Berks, Wilts, and Dorset, in a parallel line to the former.

E'SCHAR. (Gr. εσχαρα, *the crust of a scar produced by burning.*) When a living part has been burned, it becomes hard, rough, and of a grey colour, forming what is properly called an eschar: it is a slough produced by fire or caustics. The English *scar* is evidently derived from this term.

ESCHARO'TICS. Applications which form eschars. The term is generally applied in surgery to mild caustics.

ESCHE'AT, in Law, happens when tenant in fee-simple dies without having left any heir to the land, and without having incurred a forfeiture to the crown (as for treason). This case arises on sentence of death for murder; but not for other felonies, which, since 54 G. 3. c. 145., leave the power of disposition of his estate after death to the offender. In this case the land goes to the lord of the fee. There is no escheat of equitable estates.

E'SCROW. (Fr. ecreu, *scroll.*) In Law, a deed delivered to a third party, to be the deed of the party making it upon a future condition when a certain thing is performed, until which it has no effect as a deed.

E'SCUAGE, or SCUTAGE. (Either derived from scutum, *a shield*, or the same word signifying a piece of money; which latter denomination of coin, indeed, perhaps originates in the fact of money having been levied under the name of this tribute.) A pecuniary satisfaction, paid in lieu of military service by tenants in chivalry. There have been doubts among our antiquarian lawyers whether escuage were, properly speaking, a tenure in itself, or merely an incident to tenure; but the latter is probably its proper character. Littleton says, that tenant by homage, fealty, and escuage is tenant by knight service. The assessment of escuage was uncertain in amount, and, by Magna Charta and 25 Ed. 1., could only be taken by assent of parliament. Escuage, together with the other appendages of military tenures, was abolished by 12 C. 2. c. 24.

ESCU'RIAL, or EL ESCURIAL. A royal palace of Spain, about twenty-two miles from Madrid, at the foot of the Carpentani mountains, which divide the two Castiles. It was commenced by Philip II., from two motives — the dying injunction of his predecessor Charles V., who was desirous that a tomb should be constructed for the royal family of Spain; and the other to erect a monument surpassing all triumphant arches and similar buildings, to commemorate the famous victory of San Quintin, won on the festival of St. Lawrence, to whose intercession the king attributed his success. Its foundations were laid in 1563; Giovanbatista of Toledo being the architect who planned and continued to superintend the building till his death in 1567, when his pupil Giovanni d'Herrera carried on and finished it. As an architectural composition it is unworthy to be attributed, as it has been, to Bramante, Pellegrini, or Vignola. They as well as others may have given designs for it, but such were not selected. It is considered by Spaniards as entitled to be called the eighth wonder of the world; and numberless fables are told about the number of its doors, windows, and columns, as well as its cost having been twenty-four millions of ducats, though the expense of erecting it was not quite one fourth of that sum. The whole pile comprises a magnificent monastery, which was given to the fathers of San Girolamo; of a college, a seminary, and a royal palace. In plan the form resembles a gridiron, the instrument of martyrdom of St. Lawrence, of which that part used for the royal palace is supposed to represent the handle. It is internally disposed into fifteen courts of various dimensions, the largest whereof are ornamented with porticoes and galleries; and the material employed is a species of granite. The principal façade, looking towards the west, is 740 feet long, and 60 feet high to the cornice. Towers flank the façade at each angle of the edifice 200 feet high. The masses are much cut up by the division of the principal façade into no less than five stories of windows. The elevation to the east is 1100 feet long, and that to the south 580 feet long. The church of the monastery is 364 feet long, 230 feet wide, and 170 feet high; and is divided and supported by piers 53 feet distant from each other. From the centre a cupola rises of good form exteriorly, but clumsily composed inside. Its diameter is 66 feet, and from the pavement to the top of the cross the height is 330 feet. The pantheon here is a crypt under the high altar of the church, and is used as the place of sepulture of the Spanish royal family. On extraordinary occasions it is lighted by a superb lustre. The staircase leading to this mausoleum has fifty-nine steps, divided by one landing; at the sides of which are two bronze statues, — one of Human Nature stripping herself of the illusions of the crown and sceptre, the other of Hope. On the two inferior landings are two doors, — one leading to the vault, where are laid the remains of the infants and infantas, and queens who have had no issue; the other to the chamber, 36 feet diameter and 38 feet high, where the remains of the kings are deposited. The whole of the building is profusely ornamented, particularly with paintings from the best masters of Italy, Flanders, Spain, and Germany. The adjacent buildings are worthy of so august a pile. Attached to the monastery by an arched gateway is an edifice called the Campagna, which has two galleries, each 100 feet long and 20 feet wide. This was built by Francesco de Mora, the successor of Giovanni d' Herrera. Here are the hospitals, granaries, pantries, and other offices; here also are the gardens, which from being seated on the acclivity of a hill appear hanging. The garden on the south side of the monastery is 8000 feet in circuit. Adjoining the eastern and northern façades is a spacious gallery or esplanade surrounded by a parapet. On this side are the quarters for the guards, the riding school, the aqueduct, &c. &c. Beyond the outer buildings is the Fresnada, about half a league to the east. This villa is surrounded by a wall, and contains courts, gardens, meadows, fountains, trees of all sorts, lakes with islands, fisheries, &c. Here also is a church of fine and simple form, by Francesco de Mora. In 1773 many works were executed at the Escurial for the infants Don Antonio and Don Gabriele by Villaneuva, the then architect of the palace; indeed from the time of Philip II. all his successors have made some additions to this superb edifice, which, like the the original fabric, contain great beauties and great defects.

ESCU'TCHEON, or ESCOCHEON. In Heraldry, a shield on which arms are emblazoned: derived from the French écu or écusson, Italian scudo, Latin scutum. The favourite shape for the purpose of heraldry is that commonly called the Norman shield; but women, daughters of parents entitled to coat-armour, bear their father's arms on a lozenge-shaped shield. The points of the escutcheon are the parts named in order to express the local position of the charges borne on the field. (*See* CHARGE.) They are nine in number. *Escutcheon of pretence* is the shield on which a man carries the arms of his wife; in England only borne if she is an heiress, and he has children by her. It is borne in the centre of his own shield, and generally of the same shape. *Inescutcheon*, an escutcheon borne also within the shield in the middle of the coat (but smaller than an escutcheon of pretence), or in chief. It is a species of ordinary.

ESOTE'RIC, opposed to *Exoteric.* (Gr. εσω, *within*, εξω, *without.*) Much dispute has prevailed among the

learned as to the precise import of this distinction. By some it was thought that the ancient philosophers had a set of mysterious doctrines which they communicated only to the more enlightened of their disciples, and another more popular doctrine which they promulged to the multitude. In the case of Aristotle, to whose writings the distinction properly applied, this opinion is, to a certain extent, well founded; except so far as regards the suspicion of intentional concealment implied in it. The exoteric or *published* writings of that philosopher appear to have been written in the form of dialogues, all of which are lost. His esoteric works, we gather from the synonymous term *acroamatic* (*ἀκροᾶσθαι, to hear*), were not intended to supersede the necessity of oral instruction to render them intelligible. This agrees well enough with the brevity, the frequent repetitions, and the perplexed arrangement of the works of Aristotle which survive. (See *Ritter*, *Gesch. d. Ph.* b. ix. c. 1.)

E'SPALIER. In Horticulture, a substitute for a wall on which to train fruit trees, and sometimes ornamental shrubs. The objects are to expose the foliage of the plants more perfectly to the light, to prevent the branches from being blown about by the winds, and to economize space by confining them within definite limits. The espalier is either constructed of wood or iron; and commonly of two horizontal rails joined by upright rods, six or eight inches apart. The most elegant and economical structure of this kind at present in use is a double espalier formed of hoop iron posts in the shape of the letter A, twenty inches wide at bottom, and six or seven feet high, at which height the hoops meet in a point. Through the hoop iron posts wires are inserted horizontally at six inches apart, and drawn quite tight; the result of which is a double surface on which to train the trees. (See *Loudon's Suburban Gardener*, p. 232.)

ESPA'RTO. (Span.) A species of rush; the *Stipa tenacissima* of botanists. It is found in the southern provinces of Spain. It is made into cordage, much used in the Spanish navy; and is platted for other purposes, such as mats, shoes, &c.

ESPLANA'DE, or GLACIS. In Fortification, the sloping of the parapet of the counterscarp or covered way towards the open country.

ESQUI'RE, *Ecuyer*, *Escudero*. (In Latin, armiger.) A well-known title of rank; derived from the French écu, Lat. scutum, *a shield*. Some suppose that it has its origin from the Scutarii, a sort of soldiery in the Roman armies; others derive it from equus, *a horse*, and suppose that esquire and equerry denoted orignally the same thing, viz. *a groom*. But it is generally supposed to have belonged to the shield or armour bearers (armigeri) attached to the person of knights. This office, in the times of chivalry, was honourable, and generally borne by persons of good family. Hence the term esquire became gradually appropriated, in England, to a rank above the simple gentleman and below the knight. Younger sons of peers (now called Honourables), their eldest sons, eldest sons of knights, sheriffs of counties, serjeants at law, justices of the peace, and doctors of divinity, are esquires by virtue of their respective rank or office. Heads of ancient families are considered esquires by prescription; and hence has originated the use of the word, in the present day, as a common addition to the names of all those who live in the rank of gentlemen. The king creates an esquire, by putting round his neck a silver collar of *ss*; to which ceremony was formerly added the putting on of a pair of silver spurs.

E'SSAY. In Literature, an attempt; a species of composition. In general, this title is given to short disquisitions on subjects of taste, philosophy, or common life. In this sense it has been applied to periodical papers, published at regular intervals under a collective name, by one or more writers, containing remarks on topics of the day or on more serious subjects. From the appearance of the *Tatler*, in the beginning of the last century, which was chiefly written by Sir Richard Steele, this species of literature continued to be a favourite in England for seventy years, and many similar series of essays were produced; the best of which are united in one collection under the name of *The English Essayists*. The most celebrated of these works was the *Spectator*, to which Addison was the best contributor; and next to it the *Rambler*, published and almost wholly written by Samuel Johnson. The title of essay has been also adopted, by way of indicating diffidence in the completeness of their work, by various authors of more extended performances; as by Locke (*Essay on the Human Understanding*).

E'SSENCE. (Lat. essentia, from esse, *to be or exist.*) In Philosophy, a scholastic term, denoting what the Platonists called the idea of a species. The school philosophers give two significations of the word essence: the first denoting the whole essential perfection of a being, and consequently its entity, with all its intrinsic and necessary attributes taken together; the second denoting the principal or most important attributes of any thing. The essences of things were held by many to be uncreated, eternal, and immutable. *See* METAPHYSICS.

E'SSENCE D'ORIENT. A term applied to a pearly-looking matter found principally at the base of the scales of the *bleak*, a small fish of the genus *Cyprinus*: it is used to line the interior of glass bubbles or beads, as in the manufacture of artificial pearls.

ESSE'NES. A sect among the Jews in the time of our Saviour, of whom an account is preserved to us by Josephus and Philo, though they are not mentioned in Scripture. They were few in number, and lived chiefly in solitude, taking no part in public affairs, but devoting their lives to contemplation. There were indeed two classes of them, distinguished as the practical and contemplative, who differed in the degree of strictness and austerity which they observed. They believed in the immortality of the soul, and held the Scripture in the highest reverence; interpreting it, however, after an allegorical system of their own. (See *Blackwood's Mag.*, 1840.)

ESSE'NTIAL OILS, or VOLATILE OILS. Under this term are included all those peculiar compounds obtained by distilling vegetable substances with water, and which pass over along with the steam, and are afterwards condensed in the liquid or solid form. They appear to constitute the *odorous* principles of vegetables. Their specific gravity fluctuates on either side that of water: they are very sparingly soluble in water, and these solutions constitute the *medicated waters*; rose, peppermint, and other waters being such solutions of the respective essential oils. They dissolve in alcohol and form *essences*, many of which are used as perfumes. When these oils are pure, they evaporate from paper when held before the fire; but if adulterated with fixed oils, they leave a greasy stain, and seldom dissolve perfectly in alcohol. The more expensive of these oils are frequently adulterated with the cheaper ones, and this fraud can only be detected by an experienced nose. Their chief use is in perfumery, on account of their odour, and in medicine they form valuable stimulants. They are inflammable, and are, with few exceptions, compounds of hydrogen, oxygen, and carbon. The essence of turpentine, of lemons, and a few others, are *hydrocarbons*.

ESSOI'GN. In Law, an excuse for one who is summoned to appear and answer an action or perform suit in a court, &c., by reason of sickness or other prevailing cause. The first return day in every term was called the essoign day, because the court sate on it to take essoigns; *i. e.* excuses for such as did not appear according to the summons of the writ. The essoign day seems to be done away with by the effect of the statutes 11 G. 4., 1 W. 4. c. 70., and 1 W. 4. c. 3.

ESTA'BLISHMENT. *See* FOUNDATION.

ESTABLISHMENT OF THE PORT. A term used by writers on the tides, to denote the interval between the time of high water at any given port and the time of the moon's transit immediately preceding the time of high water, when the moon is in syzygy; that is, at the new or full moon. This interval is influenced by local circumstances, and consequently different at different places. *See* TIDES.

ESTAFE'TTE. (Span. estafeta.) Applied originally to military couriers, but now used in all the countries of modern Europe to signify an *express*. The difference between a courier and an estafette consists in this, that while the former must deliver the despatches, &c. entrusted to him personally at the place to which they are addressed, in the latter the despatches, letters, &c. to be forwarded are consigned to the care of postillions, who are changed with every relay of horses successively till they arrive at the place of their destination.

ESTA'TE, in common parlance, is applied to the landed property held by individuals; and a man is said to be of good or of small estate, according to the magnitude of his landed property.

Estates vary exceedingly in size and value in most parts of England. The largest estate in the kingdom may be worth 100,000*l.* or upwards a year; and there are estates of most inferior degrees of magnitude, down to the annual value of 40*s.*! In some counties property is more, and in others it is less, subdivided. In Cheshire, the East Riding of Yorkshire, and one or two other counties, there are comparatively few small proprietors; but the latter predominate in most parts of the West of England, in the North, and generally throughout the country. On the whole, we believe it may be safely affirmed, that by far the largest portion of the kingdom is parcelled into properties of less than 1000*l.* a year. It is not difficult to account for the prevalent misconceptions on this point. Though few in number, the owners of large estates engross the attention of common observers, and hinder them from fixing their eye on the mass of obscure, petty landowners, that constitute the great bulk of the class. Dr. Beeke, whose authority as to such matters is deservedly high, estimated the total number of proprietors in England and Wales at 200,000; and supposing the gross rental of the kingdom to be 30,000,000*l.* a year, the average annual income of each, in his capacity of landlord, will be only 150*l.*! and seeing that a few have much more, it follows that many must have good deal less. Hence it is

that few lead a more laborious life, or are more under the necessity of abstaining from luxurious indulgences, than the owners and occupiers of small landed properties. Nothing, in fact, can be a greater mistake than to suppose, as is generally done, that the landowners are an extremely opulent and an extremely indolent body. These may be the characteristics of a few individuals amongst them; but it would be quite as wide of the mark to affirm that they are generally applicable to the entire class, as that they are generally applicable to the classes of manufacturers and traders. (See *M'Culloch's Statistics*, vol. ii.)

ESTATE FOR LIFE, in Law, is a freehold interest in lands and tenements, whether enjoyed for the life of the tenant, or for the life of another party (in which latter case it is termed an estate pur auter vie). This species of interest includes estates granted for an uncertain period limited within the duration of a life; as, for instance, an estate granted to a widow during her widowhood. An estate for life is created wherever lands or tenements are given by means adequate to the conveyance of a freehold, without any express limitation of an estate. If tenant for life convey an estate greater than his own by feoffment, fine, or recovery, he forfeits his estate; but if he does so by any of those conveyances which are termed innocent, he creates an estate determinable on his own death. With respect to estates pur auter vie, it is observable that formerly, when lands were given to A. for the life of B., if A. or A.'s assignee happened to die in B.'s lifetime, the estate belonged to the first person who could take possession, termed an *occupant*; but if given to A. *and his heirs* for the life of B. on the same event, A.'s heir succeeded as special occupant. Now, by the Statute of Frauds (29 C. 2. c. 31. s. 12.), estates pur auter vie are devisable; and, if there be no special occupant, they go to the executors or administrator of the deceased.

ESTATE FOR YEARS. In Law, an estate limited for a term of years, or other determinate time, in lands, tenements, or hereditaments, is a chattel or personal interest; and, on the death of the owner, devolves, like other personal property, on his executors or administrator. An estate for years is properly created or *demised* by an instrument termed a lease; which, at common law, has not full operation until the entry of the tenant. It may also be created by declaration of use, or by devise in a will; and may be made either to commence immediately, or on a future day and event: in which latter case, unless there be any particular estate to support it as a remainder, it is called an *interesse termini*, until the time arrives for its reduction into possession. Covenants between the lessor and lessee, relating to the land (which are usually inserted in the lease), are said at common law to run with the land: they pass, along with the term of years, to a party to whom the lessee conveys it by assignment; but the lessee's covenants do not pass to a party to whom he conveys part of the term by underlease. A tenancy from year to year is a species of estate for years.

ESTATE OF INHERITANCE. In Law, an estate in fee-simple or fee-tail. (See these articles; and REAL PROPERTY, LAW OF.)

ESTATES, POLITICAL. *See* STATES.

ESTIVA'TION. A term applied to the parts of a flower when unexpanded: it is used, in connection with various adjectives, to express the manner in which sepals or petals are rolled up before the flower unfolds.

ESTO'PPEL. In Law, an impediment or bar to a right of action, arising from a man's own act, or that of one to whom the party estopped is privy. As, if a party is bound by a particular name in an obligation, and afterwards sued by that name on the same obligation, he is estopped, *i.e.* forbidden in law to say in abatement that he is misnamed; as he cannot say contrary to that which he has admitted by his own deed. All parties to a deed are estopped to say any thing against what is contained in it; and privies are also bound.

ESTRE'AT. In Law, the extract, copy, or note of some original writing or record, and especially of fines and amercements; entered on the rolls of the court, to be levied by its bailiff or other officer. Fines to the king are estreated into the Court of Exchequer. Estreats are made out in that court by the remembrancer for the lord treasurer, and received from him by the clerk of the estreats, who writes them out to be served for the king, &c. Provision is made for the due return, estreating, and levying of fines, &c. in the superior and some other courts by 3 & 4 W. 4. c. 99.

ES'TRICH. The commercial name of the fine down of the ostrich.

ES'TUARY. *See* ÆSTUARY.

ETÆ'RIO. In Botany, an aggregate fruit, having the ovaries distinct, pericarp indehiscent; either dry upon a fleshy receptacle, as the strawberry; or dry upon a dry receptacle, as the ranunculus; or fleshy upon a dry receptacle, as the rubus: the parts being achenia or small drupes.

ET CÆTERA, usually expressed by the sign *&c.* means *and so on.*

ETCHING. *See* ENGRAVING.

ETCHING NEEDLE. An instrument of steel with a fine point, for tracing outlines, &c. on the copper plate.

ETE'RNITY. An attribute of the Deity, the existence of whom is without beginning or end. It is the immediate consequence of the self-existence which we attribute to him. Being the cause of all things, he is himself independent of any cause.

Eternity being infinite, is inconceivable by our finite understandings; at the same time, we cannot imagine an infinite being to exist without it. There is a distinction made between an *anterior* and a *posterior* eternity. The latter belongs to creatures whom God proposes to preserve for ever; the former to himself alone. We suppose God to exist without parts, and also without succession. It is an inconsistency in atheism to suppose a succession of generations from an anterior eternity: nothing that is successive can be actually infinite and eternal.

ETESIAN WINDS. *See* WINDS.

E'THAL. A substance formed during the saponification of spermaceti. Chevreul derived the name from the first syllables of *ether* and *alcohol*, on account of its analogy to those liquids in point of composition.

E'THER. (Gr αιθηρ) In Chemistry, this term is applied to a highly volatile, fragrant, inflammable, and intoxicating liquid, produced by distilling a mixture of equal weights of sulphuric acid and alcohol. When these liquids mutually act on each other, a series of complicated changes ensue, which terminate in the conversion of alcohol into ether. Ether, like alcohol, may be regarded as a compound of hydrocarbon and water; and if alcohol be considered as consisting of *one* equivalent of olefiant hydrocarbon = 14, and *one* of water = 9, ether may be regarded as constituted of *two* of olefiant hydrocarbon $(14 \times 2) = 28$, and *one* of water = 9: hence, the equivalent of alcohol being $14 + 9 = 23$, that of ether will be $14 \times 2 = 28 + 9 = 37$; and the process of etherification may be stated to consist in the abstraction from alcohol of one half of its elemental water. By some, ether is regarded as the oxide of a peculiar hydrocarbon, which they term *ethule*, composed of 4 equivalents of carbon and 5 equivalents of hydrogen; and alcohol must in that case be considered as hydrate of ether.

Ether, or, as it is often called, to distinguish it from analogous products obtained by the intervention of other acids, *sulphuric ether*, is a limpid colourless fluid, of an agreeable odour, and a hot pungent taste. Its specific gravity is about 0·713, though that of the shops is usually heavier; it boils at about 98°, and freezes at the low temperature of 46° below 0°. The specific gravity of etherial vapour compared with atmospheric air is as 258 to 100. Ether is sparingly soluble in water, which takes up about a tenth of its bulk; it dissolves in all proportions in alcohol. The principal use of ether is in medicine. When taken internally, it is stimulant; and it is sometimes applied externally, by reason of the cold produced during its evaporation, as an ingredient in refrigerating lotions.

ETHE'RIA. (Gr. αιθω, *I shine.*) A genus of Lamellibranchiate Dimyary Bivalves, with a large ventral muscular plate or foot, as in the *Uniones*; but having their shell adherent, as in the oyster, to foreign bodies; the hinge is toothless, irregular, undulated, and callous; the ligament external, but penetrating in a pointed form into the interior of the shell. The term *Etheria* has also been applied by Rafinesque to a genus of Macrourous Crustacea.

E'THERIN. A name applied by some chemists to quadrihydrocarbon; that is, to an hydrocarbon 1 atom or equivalent of which is constituted of 4 atoms of carbon and 4 of hydrogen. It is obvious that such a compound may be regarded as the base of ether; its equivalent would be $6 \times 4 = 24 + 4 = 28$.

E'THICS. (Gr. ηθος, *custom, moral character*.) The science the object of which is to determine what ought to be in relation to voluntary action, and to those dispositions, faculties, or affections of mind which tend mediately or immediately to voluntary action. It has been our aim throughout the present work, in all articles relating to abstract or speculative subjects, especially to such as have been matter of long controversy, rather to present our readers with a history of the opinions which have been held by others, and to direct them to the works in which those opinions are maintained with the greatest ability, than to give a systematic account of what appeared to us the correct view of the particular department of inquiry before us. The definition with which we preface this article may appear to be in some degree a deviation from this our practice, inasmuch as it contains by implication a decision of certain questions in the science before us, which some of our readers may consider to be still "sub judice," besides including the use of terms to which it has been asserted by certain modern writers on ethics that no intelligible meaning can be attached. Our answer is, that we can conceive of no definition, not including the terms in question, or their equivalents, which shall justify us in assigning to the science of ethics an independent existence, or, by consequence, in giving to

the word which designates it a distinct place and a separate treatment. Whether the words "ought" and "voluntary" have any meaning or not, must appear from the sequel: it is enough for our present purpose that the majority of moralists have believed them to possess one.

There is no subject within the limits of speculation concerning which controversy has been waged with greater vehemence, with the exception, perhaps, of theology, than that of ethics. We have not far to search for the general reasons of this fact. Besides being a science of pre-eminent interest to those who unite high moral feeling and a concern for the interests of their kind with a capacity for speculation, it is a science also the treatment of which is peculiarly liable to be affected by the moral nature and habits of those who take it in hand. Without taking upon us to assert that to be a good ethical writer it is necessary to be a good man, we think that the history of speculation justifies us in the belief that a partial or confined view of moral science indicates, for the most part, a corresponding excess or defect in the moral qualities of the person holding it; at least where such peculiarity cannot be traced either to imperfect intellectual qualifications, or to singularly unfavourable circumstances of time, place, or education. Systems which have sprung up under such influences commonly expire with the circumstances which called them into being. The youthful student may indeed be attracted by the ingenuity or confounded by the subtlety with which they have been maintained; but, with a person of sound mind, who has access to writers of larger and deeper views, they cannot long maintain a place in his understanding, much less in his practical habits. We have introduced these remarks, partly as our justification for omitting from this article all notice of such systems as those of Epicurus in ancient, and Hobbes, Helvetius, and Mandeville in modern times; and partly as an introduction to what we shall make the central point of our observations—an account of the controversy which at present divides ethical speculators in England. We allude, it will be perceived, to the dispute which has for some time prevailed between the respective partizans of what have been called the "utilitarian" and "sentimental" schools. Those who are acquainted with the most recent records of opinion which have been published on both sides of this controversy will see reason to wonder at two things: at the very small real discrepancy between the parties engaged; and at the singular vehemence with which they disclaim all community of opinion, and strive to establish a difference which does not exist, or to exaggerate one which does. An historical examination of the origin and growth of the two schools will in a great degree explain these two facts; inasmuch as it will show that the difference between the disputants is one rather of feeling and habit than of pure theory. It will also serve as a thread whereon to hang such notices of past systems as it was necessary to give, in order to impart to this article the same historical character with that possessed by the articles on similar subjects which occur during the course of this work. We shall thus have an opportunity of communicating to our readers by far the most of what is really important in English ethical speculation; and in the attempt which we shall make to show the essential incompleteness of both theories, and to indicate the true central point from which the science of morals ought to be viewed, we shall be enabled to introduce an account of some of the leading features which distinguished the systems of antiquity. We begin with those whom we have named the sentimental moralists.

The most eminent of these have been men who have devoted their attention chiefly or entirely to what may be called empirical psychology; that science, namely, which determines the sequences of mental phenomena, and their dependence on each other in the relation of cause and effect; in one word, to the *physics* of the mind. In this department of science the most fruitful discovery that has been made is what is commonly named the Law of Association. This law, according to which Hobbes and Condillac attempted to account for the origin of our perceptive and intellectual faculties, was applied with better success by Hartley to the analysis of our emotive principles. The moral sentiments, the ultimate source of which Hutchison held to be benevolence, and Adam Smith sympathy, Hartley sought still lower, in the simple capacity of organic pleasure and pain. From these original elements are formed, by successive or co-ordinate processes of association, the feelings of sympathy, gratitude, resentment, shame, and the like; and, as the last and most perfect formation, the faculty of moral approbation or disapprobation. This theory, which must not be, as it frequently is, confounded with the selfish theory, is that which the celebrated dissertation of the late Sir James Mackintosh, prefixed to the *Encyclopædia Britannica*, is intended to illustrate. It is in reference to the successive stages of development of the associative principle that this elegant work is alone valuable. Its author may be considered as ending the series of sentimental moralists; in which, in addition to the names given above, may be inserted that of Dr. Thomas Brown. The result of their speculations is, that they have established the existence of a moral faculty in man, as a fact of natural history; a fact, also, which holds a distinct and defined place in a physical theory. It is, as we shall see, by no means an insignificant circumstance that, of the five names we have enumerated, two were physicians by profession, and one had dedicated great part of his youth to the study of practical medicine.

The reputed father of the "utilitarian" moralists is the celebrated Jeremy Bentham. The labours of this unquestionably powerful thinker were principally devoted to the sciences of legislation and jurisprudence; to which, also, much of the attention of those who profess themselves his followers or admirers has been directed. It is only as auxiliary to these sciences that Mr. Bentham has handled the subject of morality. The most complete account of the utilitarian principle is to be found in Mr. Austin's work on jurisprudence. This principle is thus enunciated:—"The morality or immorality of an act consists in the beneficial or pernicious consequences resulting from it; the morality or immorality of an agent, in the goodness or badness of his intention, the goodness or badness of the intention being determined by the nature of the consequences which are foreseen, or might be foreseen, as resulting from the act." Here, we are told, we must carefully distinguish between *intention* and *motive;* between foresight of the consequences of an action, and the state of mind which causes the action. To quote an instance used by the acute author of a recent work named *A Fragment on Mackintosh*,—"A man, to save his family from starving, wires a hare on my estate. My first impulse is to throw him into jail. Before I determine to do so, however, I consider the misery which I shall bring on the man himself, and the state of want, wretchedness, and probable demoralization, into which I shall plunge his family. In spite of these foreseen consequences, I resolve to prosecute him. Here my *motive* is the preservation of my game, my *intention* the production of misery and vice in a multitude of my fellow-creatures. The immorality of this act manifestly consists in the intention; the motive is neither moral nor immoral." Having given this preparatory illustration, we shall extract from the same work what is there denominated "A list of the requisites of a moral act." These are—"1. *The motive.* There is no act without a motive; but the motive is in itself neither moral nor immoral. 2. *The volition.* There is no act which is not willed; but the act of willing is neither moral nor immoral. 3. *What is called the external act;* to wit, *the bodily part or motive.* That, like the motive, is in itself neither moral nor immoral. The same bodily operation is indifferently a part of every sort of act. It is, however, a necessary part of every act. 4. *The consequences of the act.* An act which has no consequences that are materially either beneficial or hurtful is not called a moral act. That alone receives this denomination which has consequences material to some one or more human beings. 5. *The expectation of the beneficial consequences in the mind of the agent* 6 This is not all: it is not enough to make an act moral that the agent expects from it beneficial consequences to somebody; it is further necessary *that he have no reason to expect from it evil consequences equivalent* to any other body; that is, in other words, that he have *a conviction of its general utility.*"

In order to obviate an objection to the principle so enunciated,—viz. that it supposes a laborious calculation of consequences to precede every moral action,—Mr. Austin, in the work to which we previously alluded (*The Province of Jurisprudence Determined*), qualifies the statement by the admission that the principle of utility itself requires that our conduct should be guided by *general rules,* formed according to the principle of utility, and not by an immediate appeal to utility itself in each particular instance. Thus qualified, the principle is precisely the same with that laid down by Kant, as the "groundland of the pure practical reason:"—"Act so that the maxims of thy will, in each particular instance, may hold equally as the principle of a universal legislation." And this philosopher, in common with the English utilitarians, regards this principle as a postulate which lies at the foundation of morality. Thus explained, it will be seen that there is no theoretical inconsistency between the utilitarian and sentimental moralists. Sir James Mackintosh expressly admits that the only criterion of morality in action,—that is, the only criterion by which right and wrong in human conduct can be determined,—is the consequences of such conduct on the happiness of mankind. It has been with reason objected, that the second department of the two into which he divides the science of ethics, "the nature of those feelings with which right and wrong are contemplated by human beings," does not in itself belong to morality at all. It is in truth a part of psychology, and nothing more, and that by his own admission, that the purpose of moral science is "to answer the question '*what ought to be.*'" The *obligation* of the rule of action is the same, whatever are the feelings with

which we may happen to regard right and wrong; and whatever may be their origin, and the process of their formation. That the nature of these feelings ought to be made an important item in every calculation of the consequences of our actions, would be admitted by any consistent utilitarian who is capable of such considerations, and that in obedience to his own principle. The science of psychology is admitted by such persons to be a valuable auxiliary to that of ethics, and as such has been elaborately treated by Mr. Mill, in his *Analysis of the Human Mind*. This we conceive to be all that Sir James Mackintosh, in the principles of his general philosophy, had a right to claim for that branch of science, to the elucidation of which he has devoted by far the greater part of his dissertation. The relation between utilitarianism and sentimentalism may consequently be expressed thus: It is our duty so to frame our conduct, that it may contribute as much as possible to the happiness of mankind. The happiness of a man consists, as experience proves, not in the gratification of one or two desires, but of as many as possible. But the more faculties a man can exercise the more numerous are his desires, and the greater the happiness of which he is capable; consequently, it is our duty to contribute as much as we can to the development of the faculties of all with whom we have to do: the means to this end are supplied by the science of experimental psychology, including the doctrine of the formation, among other faculties, of the moral sentiments.

The question now arrives, is this a complete theory of morals? We think not; and we will proceed to state our reasons for this opinion. It will be admitted, that in order to conceive of the existence of a particular class of pleasures, and by consequence of a particular class of faculties or desires of which these pleasures are the exercise or the gratification, we must be conscious of the existence of the same class in our own constitution. What is true of one class is true of all. Before, therefore, we can take upon us to determine wherein the *greatest* happiness of man consists, we must take care that our idea of human nature be a complete one; we must see to it that we leave out of consideration no element in the constitution of man. Nor is this enough. It will be admitted, as a fact of experience, that the gratification of certain of our desires does, if carried beyond certain bounds, impair and interfere with the free action of certain other equally important sources of enjoyment. Consequently, what is true of the constitution of a state is true, likewise, of the constitution of man: the action of its constituent parts requires to be determined by some measure or law which shall appoint to each the sphere and limits of its exercise. The Greek philosophers, who, whatever may be their deficiencies in subordinate inquiries, saw more distinctly than any before or since the true problems which philosophy ought to solve, have pointed to this law under different names—whether of the *chief good*, the *rule of right*, the *harmony of the soul*, or the like—as the great difficulty of ethics to the clearing up of which all other inquiries ought to be regarded as subordinate and tributary. Of all the moralists of antiquity Plato perceived this with the greatest clearness. His *Republic* is meant as an approximation to the determination of this law, alike in the individual and in the state. That we may not be accused of blind veneration for antiquity, we will adduce the most celebrated ethical writer of the last century in our justification. Those of our readers who have formed their conception of the objects of Bishop Butler's moral writings from the strangely partial view of them taken in Sir James Mackintosh's dissertation, will probably be surprised to hear that his is the name to which we allude. The preface which he has prefixed to his *Sermons* is intended as a brief preliminary statement of what he calls "the occasion, scope, or drift" of the detached inquiries which follow. Of what this scope or drift was we are bound to accept his own account; and before we can rightly apprehend it, he tells us we must "begin by stating to ourselves exactly the idea of a system, economy, or constitution, of any particular nature, or particular anything. We shall, I suppose, find that it is a one, or a whole, made up of several parts; but yet that the several parts, even considered as a whole, do not complete the idea, unless in the notion of a whole you include the relations and respects which these parts have to each other. Every work, both of nature and art, is a system; and as every particular thing, both natural and artificial, is for some use or purpose out of and beyond itself, one may add, to what has been already brought into the idea of a system, its conduciveness to this one or more ends. Let us instance a watch: Suppose the several parts of it taken to pieces, and placed apart from each other; let a man have ever so exact a notion of these several parts, unless he considers the respects and relations which they have to each other, he will not have anything like the idea of a watch. Suppose these several parts brought together and united anyhow; neither will he yet, be the union ever so close, have an idea which will bear any resemblance to that of a watch. But let him view those several parts put together, or consider them as to be put together in the manner of a watch; let him form a notion of the relations which those several parts have to each other—all conducive in their respective ways to this purpose, showing the hour of the day; and then he has the *idea* of a watch. Thus it is with regard to the inward frame of man. Appetites, passions, affections, and the principle of reflection, considered merely as the se eral parts of our inward nature, *do not at all give us the idea of the system or constitution of this nature; because the constitution is formed by somewhat not yet taken into consideration, namely, by the relations which these several parts have to each other*." Bishop Butler goes on to remark, that "what in fact or event commonly happens is nothing to this question;" for, "one may determine what course of action the economy of man's nature requires, without so much as knowing in what degrees of *strength* the several principles prevail, or which of them have actually the greatest influence." But between a machine and a man, says Butler, in allusion to the illustration from the watch, "there is a difference too important ever to be omitted. A machine is inanimate and passive; but we are agents. Our constitution is put in our own power. We are charged with it; and therefore are accountable for any disorder or violation of it." The inference which an impartial reader of these quotations, after comparing them with the *Sermons on Human Nature*, will necessarily draw is this, that not only has Butler's object and purpose been misconceived by Mackintosh, but that it was an object which, consistently with the rest of his philosophy, Mackintosh must have held to be unattainable. For it implies two things: first, that in order to complete the rule of human action, we must have an idea of perfect humanity; secondly, that before such rule can be binding upon man, we must show, not only that he *feels himself* or may be made to feel himself, but that he really *is*, accountable for its violation. Whether these two questions can be adequately disposed of without the introduction of higher, that is, of theological or metaphysical considerations, is a matter which each man must decide according to the tenor of his general philosophy. The former of the two was so distinctly perceived by Aristotle, that his whole ethical system must be viewed in reference to it; the latter lies at the root of the moral philosophy of Kant. Until the first is disposed of, the rule of action is implicated in an inevitable circle; without the second, no rule can be shown to be obligatory, and ethics can no longer be distinguished on the one hand from the history of internal, on the other from that of external, phenomena.

E'THIOPS MINERAL. The black powder obtained by rubbing mercury with sulphur.

ETHMOI'D. (Gr. ἠθμος, *a sieve*, and ειδος, *form*.) The ethmoid or cribriform bone. A bone of the head enclosed in the *os frontis*, between the orbitary processes; it is very light and spongy, and consists of a network of convoluted plates.

ETHNO'GRAPHY. (Gr. ἔθνος, *nation*, and γράφω, *I describe*.) The science which treats of the particularities of nations, describing their customs, peculiarities, &c. Although a peculiar name has been given to it, it is in general considered as a branch of the sciences of geography and history. (See *Balbi's Ethnography*.)

ETHU'LE. (Gr. αιθηρ, and υλη, *principle*.) A term applied by Berzelius to the elementary carbon and hydrogen of ether; he regards ether as an oxide of a compound of 5 equivalents of hydrogen and 4 of carbon.

E'TIOLA'TION, or CHLOROSIS, is that condition of a plant in which all the green colour is absent. Such a state is produced by want of light, and is artificially obtained by keeping plants in the dark in order to ensure their being more tender and insipid than is natural to them. Etiolated parts become green by exposure to light.

ETIQUE'TTE. (Fr. a ticket.) Is the ceremonial code of polite life, more voluminous and minute in each portion of society according to its rank. The word is derived from the custom of arranging places at processions, &c. by tickets delivered beforehand to applicants. The Byzantine court appears to have carried the practice of ceremonial observances to the most inconvenient and ludicrous extent. But of modern courtly etiquette, Philip the Good, Duke of Burgundy, is regarded by some as the founder (see *Conversations Lexicon*). His desire to conceal his inferiority in rank (as a great feudatory only) to the great sovereigns of Europe, whom he equalled in power, induced him to surround his presence with a multitude of officers and numberless formalities. At no time, probably, was the spirit of etiquette so predominant and so tyrannical as in the court of Louis XIV.; and the *Memoirs of Saint Simon* are full of the most extraordinary proofs of the subjugation of the minds of men of sense, wit, and even independent character in other respects, to its engrossing influence,—their pride in attaining any little point of precedence, and their mortification in failing of it. The smaller courts of Germany caricatured the ceremonial of that of the Great Monarch, and carried its strictness to an absurd extent. At the present day the ancient

etiquette of courts is continually losing something of its strictness.

ETYMO'LOGY. (Gr. ἔτυμος, *true*, and λογος, *description*, &c.) The science which treats of the origin or root of individual words, and of the relation borne respectively by their several meanings to that origin. It is a branch of the general science of philology. *See* PHILOLOGY.

EU'CHARIST. (Gr. εὐχαριστια.) Signifying properly giving of thanks, but generally used in theological language to denote the sacrament of the Lord's Supper. The celebration of this rite is derived from the account given by the Evangelists of the action of our Lord in offering to the apostles bread and wine, saying at the same time, "Take and eat, this is my body;" and "Drink ye all of this, for this is my blood of the new testament, which is shed for many for the remission of sins;" and adding at the same time, "Do this as oft as ye shall do it in remembrance of me." This commemoration is spoken of in the N. T. and by the Fathers as a sacrament and a mystery; it must be supposed, therefore, that there is an interior signification conveyed under our Saviour's words—a further effect to be derived from the communion in the bread and wine besides that which is obvious and external. Under the head of TRANSUBSTANTIATION will be found the solution which the Roman Catholics discover for this mystery. Consubstantiation, or the simultaneous presence of the body and blood with the bread and wine, is the attempt made by Luther to explain the operation of a divine mystery according to the literal interpretation of Scripture. According to the doctrine of the Anglican church, there is an inward and spiritual grace conveyed in the Eucharist to those who partake of it; and it is in this that our church differs from many Protestant communities, who conceive the communion to be nothing more than an outward act of obedience enjoined upon us as a commemorative ceremony, and only instrumental to our salvation in the same way as any other act of obedience. *See* SACRAMENT.

It is common in the Fathers to meet with the term sacrifice applied to the Eucharist, and this has been considered by the Romanists as favouring their view of its nature. They appeal also to the prophecy of Malachi, which alludes to a pure offering or an unbloody sacrifice, which shall be offered up to the Lord from the rising to the setting of the sun; and maintain, therefore, that the consecrated elements are offerings made to God for the sins of the people, in the same sense as the expiatory sacrifices of the Jewish law, and not merely commemorative tokens. From hence follows the supposed necessity of the sacrifice of the Mass, and its efficacy for the absent, or even dead, and the mediatorial character attributed in the Romish church to the priest. The Protestants, however, while they do not deny the applicability of the word sacrifice to the Eucharist, restrict it to one of the senses which it bears in the Hebrew phraseology; and consider the pure offering prophesied by Malachi to be an offering of prayer and thanksgiving, such as is constantly referred to by the Psalmist; as, CXLI. 2., "Let my prayer be set forth before thee as incense, and the rising up of my hands as the evening sacrifice;" LI. 17., "The sacrifices of God are a broken spirit," &c. The seventh chapter of Hebrews is considered decisive against the mediatorial character of the Christian priest; and the Eucharist is held by the church of England to be not a propitiatory but a commemorative sacrifice—a federal act of professing our belief in the death of Christ, and of renewing our baptismal covenant with him; and endued with virtue to confer grace upon those who partake of it sincerely and devoutly.

EU'CHLORINE. (Gr. ευ, *very*, and χλωρος, *green*.) A name given by Sir H. Davy to the oxide of chlorine, in consequence of its deep yellow-green colour.

EUCHO'LOGY. (Gr. ευχη, *prayer*, and λεγω, *I collect*.) A book of prayers; synonymous, in the phraseology of the Roman Catholic church, with *missal* or *breviary*.

EUCLA'SE. (Gr. ευ, *well*, and κλαω, *I break*.) A very rare mineral, brought in small greenish crystals from Peru and Brazil. It is a silicate of glucina and alumina.

EU'CRASY. (Gr. ευ, and κρασις, *temperature*.) An agreeable well-proportioned mixture of qualities, by which a body is said to be in good order, and disposed for a good state of health.

EUDIO'METER. (Gr. ευδια, *calm air*, and μετρον, *measure*.) This term is generally applied to instruments for facilitating the analysis of atmospheric air, or rather for determining the quantity of oxygen contained in a given volume of air; under the idea that the salubrity of air depended upon its relative quantity of oxygen. We now know, however, that this is not the case, and that the relation of the oxygen to the nitrogen in the atmosphere is not subject to any discernible fluctuation.

EU'LABES. (Gr. ευλαβής, *timid*.) A genus of Passerine birds, belonging to the family of thrushes, and distinguished by having broad strips of naked skin on each side of the occiput, and a bald spot on the cheek. The bill nearly resembles that of a thrush; their nostrils are round and smooth. The species are termed *Mainates* by the French ornithologists; and the Javan *mainate* (*Eulabes javamens*) of all birds is said to imitate most completely the language of man.

EULI'MA. (Derivation unknown.) A genus of marine shell-clad Gastropods, whose characters are *shell* turreted, acuminate, with many whorls; aperture ovate, acuminated posteriorly; outer lip thickened, and bearing numerous obsolete *varices* or wart-like processes; operculum horny, thin, and with its nucleus anterior.

EU'LOGY. (Gr. ευ, *well*, and λεγω, *I speak*.) In a general sense, an encomium pronounced on any person for his meritorious or virtuous qualities; but, in a more restricted meaning, it was used in ecclesiastical history to denote any present bestowed on the church after having been *blessed* or *hallowed*.

EUNI'CE. (Gr. The name of a Nereid in *Apollodorus*.) A genus of Marine Dorsibranchiate Anellidans, having tufted branchia, and a mouth armed with three pairs of horny jaws. One species (*Eunice gigantea*) attains the enormous length of between four and five feet.

EU'NUCH. (Gr. ευνη, *a bed*, and εχειν, in the sense of *to have the care of*.) A term applied to those who have been subjected to the operation of castration. The fortunes of such individuals form an eventful chapter in the history of the human race; whether we consider the purposes for which the operation was performed, or the numbers of those who have undergone it. This practice seems to have originated in the jealousy which prevails in eastern countries. As far back as the time of Herodotus, it was carried to a great extent by the Persians, who not merely intrusted to eunuchs the care of their wives and daughters, but considered them in every respect as more trustworthy than other individuals. In the middle ages the "chief of the eunuchs" was one of the most important functionaries of eastern government; and the seraglios of these countries are superintended by eunuchs even in the present day. In modern times the loss of virility is in some countries believed to preserve and improve the voice; and hence, especially in Italy, this operation is practised upon children intended to supply the operas of Europe with singers. Zeal for religion has also caused many persons to undergo this operation, in the view of guarding themselves from sensual pleasures. As early as the third century there arose a class of enthusiasts, who, animated by the example of Origen, not only castrated those of their own persuasion, but even all persons on whom they could lay their hands. Several of the Christian Roman emperors instituted severe prohibitions against this revolting practice; and at a later period the Council of Nice excluded from the pale of the church all who, actuated by whatever motives, had allowed themselves to be thus mutilated.

EUPA'TRIDÆ. (Gr. ευπάτριδαι.) In Ancient History, the nobles of Attica, in whose hands in early times all the power of government was vested, in consequence of which the lower orders sunk into a low state of degradation, being particularly oppressed by their debts which the pressure of their circumstances compelled them to incur, and which, if not paid, gave the creditor power over the bodies and liberties of the debtor and his family. These evils were remedied by the legislation of Solon, who reduced the interest of debts, and deprived the creditor of his power over the body of the debtor, and at the same time threw the judicial and much of the legislative power into the hands of the people at large or Demus (Δῆμος). The alterations in the constitution of Athens subsequent to the time of Solon by degrees deprived the Eupatridæ of all their political privileges, and finally established an unmixed democracy.

EU'PHEMISM. (Gr. ευφημειν, *to speak well of a person or thing*.) A figure in rhetoric, by which one expression is substituted for another, conveying, through some association of ideas, an image offensive to the hearer or reader. In classical writers, euphemism often arises from a superstitious avoidance of certain words and phrases; and among ourselves similar fastidiousness prevails on some points, as in the constant use of the words "deceased" and "departed" for "dead."

EU'PHONY (Gr. ευ, *well*, and φωνη, *sound*), in contradistinction to *Cacophony* (quod vide). That agreeable quality in language which results from happy combinations of the enunciative elements; such especially as, though essentially different in their characteristic powers, melt easily into each other, so as to preserve an uninterrupted flow through the respective members of a sentence, without labour to the speaker or offence to the hearer. No rules can be laid down to ensure this agreeable quality in composition: his taste, ear, and discrimination must be the guide of every writer.

EUPHORBIA'CEÆ. (Euphorbia, one of the genera.) A natural order of Exogenous plants, inhabitants of almost all parts of the globe; nearly allied to *Malvaceæ* and *Rhamnaceæ*, especially agreeing with the former in the starry structure of the hairs, the monadelphous stamens, and the definite number of ovules in three united

carpels. Their sensible properties are, on the whole, poisonous and exciting, both being of a volatile nature and often dispelled by heat. Thus the stem of *Jatropha manihot*, or *Cassava*, which, when raw, is one of the most violent of poisons, becomes a wholesome nutritious food when roasted: in the seeds the albumen is harmless and eatable, but the embryo itself is acrid and dangerous. Independently of the volatile principle there are two others, — viz. 1. Caoutchouc, the most innocuous of all substances, produced by the most poisonous of all families. 2. Turnsol, the bark of several crotons, the wood of *Croton tiglium* and common box, — the leaves of the latter, of *Cicca disticha*, and of several euphorbias, are sudorific, — and many other species, amongst which *Ricinus* may be mentioned, are purgative: the latter produces from its seeds by pressure the well-known castor oil.

EUPHO'RBIUM. (From Euphorbus, physician to king Juba, in honour of whom the plant was named.) An acrid gum resin, the produce of the *Euphorbia officinalis;* it is virulently purgative and emetic, and the dust of it is dangerously stimulant to the nose.

EU'PION. (Gr. ευ, *very*, and πιων, *greasy*.) A very limpid liquid which stains paper like oil, and which exists in the tar produced during the destructive distillation of animal and vegetable substances. Its specific gravity is 0·74, and it boils and evaporates at 340°. It is insoluble in water, but dissolves in ether and alcohol. It is insipid and inodorous, but highly inflammable.

EURI'PUS. (Gr. ευριπος.) In Ancient Architecture, the space which separatedthe arena from the seats in the circus.

EURO'PA. In Fabulous History, the daughter of Agenor, king of Sidon. She is represented as having been of such surpassing beauty that Jupiter became enamoured of her. In order to gain her affection the god transformed himself into a bull of wonderful whiteness, and while Europa was gathering flowers in a meadow near the sea shore, mingled with her father's herds. The virgin, attracted by the beauty of the bull, began to caress him; and at length, in the playfulness of youth, ventured to get on his back. Upon which the bull, taking advantage of her situation, made a retreat towards the sea, through which he carried her in safety. Arrived in Crete, the god resumed his real form, and declared his passion, which was returned; and from their connection sprang Minos, Rhadamanthus, and Æacus, the celebrated Elysian judges. The simple statement of Herodotus, that Europa was carried off by some Cretan merchants, who, according to some authors, arrived at Sidon for mercantile purposes with a ship bearing a white bull on its prow, but, according to Diodorus, with a commander named Taurus (bull), offers one of many probable solutions of this fabulous story. From her, according to mythologists, the quarter of the globe which we inhabit received its name. The word is possibly derived from Gr. ευρυς, *large*, and ωψ, *the eye;* large eyes having been regarded by the Greeks as a mark of great beauty.

EURY'DICE. In Fabulous History. *See* Orpheus.

EURY'THMY. (Gr. ευρυθμια, *justness of proportion*.) In Architecture, the regular, just, and symmetrical measure resulting from harmony in the proportions of a building or order. It is one of the six essentials of Vitruvius.

EUSTA'CHIAN TUBE. Named after the celebrated Italian anatomist Bartholomew Eustachius, who is said to have discovered it, though it is accurately described by Aristotle, who quotes an earlier Greek anatomist, Alcmeon, as having known it. This communication between the ear and the mouth begins in the anterior part of the tympanum, and runs in a bony canal forwards and inwards, terminating with the petrous portion of the temporal bone. It then proceeds, partly cartilaginous and partly membranous. gradually enlarging to its termination behind the soft palate. It is through this tube of communication with the ear that persons who have a perforated tympanum blow tobacco smoke: when the Eustachian tube is stopped or obliterated it produces deafness.

EUSTA'CHIAN VALVE. A semilunar membranous valve, which separates the right auricle of the heart from the inferior *vena cava*, first described by Eustachius.

EUSTA'THIANS. A sect of heretics of the 4th century; so called from their founder Eustathius, a monk whose opinions were condemned at the council of Gangea.

EU'STYLE. (Gr. ευ, *well*, and στυλος, *column*.) In Architecture, that species of intercolumniation or space between columns, which, as the name imports, the ancients considered the most beautiful, and which Vitruvius says exceeded all others in strength, convenience, and beauty; it was two diameters and a quarter of the column in width.

EUTE'RPE. (Gr. ευ, and τερπω, *I delight*.) In Mythology, the muse which presided over wind instruments.

Si neque tibias
Euterpe cohibet, nec Polyhymnia
Lesboum refugit tendere barbiton. (*Hor.* Ode I. l. 54.)

To this muse is ascribed also the invention of tragedy.

EUTHANA'SIA. (Gr. ευ, and θανατος, *death*.) Literally, an easy death. By political writers it is employed in various senses to indicate such peculiar theories as have the best tendency to uphold the state or disentangle it from difficulties. Thus, for instance, it is maintained that the issue of inconvertible paper money is the true *euthanasia* of public debts in modern countries.

EUTY'CHIANS. A sect of the fifth century, who appear to have been seduced into an erroneous view of the nature of Christ by the vehemence of their opposition to the heresy of the Nestorians. These latter had asserted the distinctness of the two natures in Christ; the Eutychians confounded them together, and supposed the human to be merged in the divine. Their originator, Eutyches, was the abbot of a monastery at Constantinople, and was excommunicated in the year 448 by a synod which was convened there for that purpose. This decision was controverted by another council at Ephesus in the following year; but the new opinions were finally condemned by the council of Chalcedon in 451, which established the orthodox doctrine that Christ was perfect God and perfect man, consubstantial with the Father as to his divinity, and with man as to his humanity, the two natures being united in him without conversion, without confusion, and without division.

EVANGE'LICAL CHURCH. (Gr. ευαγγελιον, *gospel*, literally good tidings: from ευ, *well*, and αγγελος, *messenger*.) The different Protestant sects of Germany assume this general title, implying their reliance on the Bible alone as the rule of faith: it more especially designates the Lutheran church.

EVA'NGELIST. (Gr. ευαγγελιστης.) One who brings good tidings. Hence the authors of the Four Gospels are called Evangelists.

EVA'NTES. Priests of Bacchus; so called from their usual exclamation during their orgies, "ohe evan."

EVAPORA'TION. The conversion of substances into vapour is one of the most important and general effects of heat. During this process, a considerable quantity of sensible heat passes into the *latent* or insensible state. When a vessel of water is placed upon the fire, its temperature gradually rises till it attains 212°; then, although it remains upon the fire, and of course receives heat as before, it does not become hotter, but is gradually converted into steam or vapour: so that the effect of heat is not to elevate temperature, but to change state or form; that is, in the case of water, to convert it into steam. Hence we assume that steam, though not hotter than water, contains a much larger quantity of heat, and this heat again makes its appearance when the steam is condensed or re-converted into water. At whatever temperature vapour is produced, it is similarly constituted; and that which escapes from water at ordinary temperatures, by the process usually called *spontaneous evaporation*, resembles the former in all respects: hence it is that evaporation is to surrounding bodies a cooling process; and that in the converse change, or the return of the vapour to the liquid state, heat is evolved and rendered sensible. The same general phenomena are observed with all other liquids, and those which evaporate rapidly at common temperatures often give rise to the production of a great degree of cold; such as spirit of wine, or ether. If the latter fluid be suffered to dribble over the bulb of a thermometer, it will cause it to sink below the freezing point of water; and by accelerating similar cases of evaporation, we obtain most intense degrees of artificial cold.

The circumstances that principally influence the process of evaporation are, extent of surface, and the state of the air as to temperature, dryness, stillness, and density.

EVE'CTION. (Lat. eveho, *I raise up*.) An inequality of the moon's motion, depending on the position of the transverse axis of the lunar orbit in respect of the line of the syzygies, or line joining the sun and earth. When the transverse axis lies in the same direction with that line, the quantity by which the solar force diminishes the gravitation of the moon is greatest when the moon is in the apogee, and least in the perigee. In this situation of the orbit, therefore, the difference between the moon's gravitation at her apogee and perigee is increased by the solar action, and the orbit consequently appears to have its eccentricity augmented. When the line of the apsides is in the quadratures, the contrary happens; the difference between the amount of gravitation at the apogee and perigee is diminished, and the eccentricity of the orbit appears also to be diminished. The evection is proportional to the sine of twice the angular distance between the sun and moon, diminished by the moon's mean anomaly; and its greatest value amounts to 1° 20′ 29·9.″ This inequality (sometimes called the *second* inequality of the moon's motion, the equation of the centre being the *first*) was noticed by Hipparchus, and Ptolemy gave a construction which represents its general effects with great accuracy. The term *evection* was first applied to it by Bullialdus.

E'VEN KEEL. A ship is said to be on an even keel, properly speaking, when she draws the same water abaft as forward; the expression, however, often implies, though inaccurately, not inclined to either side, or upright.

E'VERGREEN. A name applied to those plants whose leaves remain perfect upon a stem beyond a single season; as the *Ilex aquifolium*.

E'VIDENCE. In Law, has been defined "any matter of fact, the effect, tendency, or design of which, when presented to the mind, is to produce a persuasion, affirmation, or disaffirmation of the existence of some other matter of fact."

A witness, in a court of common law, is compelled to give his attendance, in civil cases, by subpœna, or by habeas corpus if the witness be in custody. The reasonable expenses both of going and returning must be tendered to the witness when he is served with the subpœna. A witness, refusing to attend on subpœna, may be attached for contempt of court, and is liable to an action at the suit of the party damaged. In criminal cases, the attendance of a witness for the prosecution is enforced either by subpœna, or more usually by the magistrates who take the depositions in the first instance binding him over to appear. His expenses, in a case of felony, are ensured to him by statute. The defendant may compel attendance of his witnesses by subpœna.

When the witness appears in court, objections may be taken to his competency; and those arising from his ignorance or unbelief, or turpitude of character, ought, in the usual course, to be taken before he is sworn.

Incompetency. — 1. Incompetency from defect of religious principle is where the witness disbelieves or is ignorant of the existence of a God, and of a future state of rewards and punishments. Infidels, therefore, are excluded; but no others of whatsoever sect or opinion. 2. Incompetency from turpitude arises from a conviction for treason, felony, and several misdemeanors; but is removed by pardon, or by reversal of the judgment, or by endurance of the punishment awarded by the sentence. 3. The next source of incompetency is interest; and the general rule on this subject is, that a party is disqualified only by a direct and certain interest in the event of the suit. But it will be obvious that the distinctions arising out of so general a proposition are infinitely minute, and create constant difficulty in practice. The following are a few of the leading rules:—

All parties to the suit, although but nominal, are excluded from giving evidence. A prosecutor, in a criminal case, is not a party, nor directly interested in the verdict, and is consequently admitted. A person to whom a liability would immediately result from the verdict is incompetent to give evidence for the party in whose success he is interested; as, for instance, one who has guaranteed a party against the event of the suit; or a co-partner; or an agent liable to his principal, in the case where a principal is sued for any damage arising from the agent's neglect. A witness is also incompetent where he has an interest in the record; that is to say, where the judgment of the court, if his party succeeded, would be evidence of a matter of fact to entitle him to some legal advantage. In criminal proceedings, however, no verdict obtained wholly or partly on the testimony of any witness can be evidence for or against that witness in any other proceeding; and therefore he cannot be objected to on that ground. Some exceptions also to this rule of exclusion arise from the necessity of the case: upon this principle the testimony of the servants of tradesmen, to prove the delivery of goods and payment of money, is daily admitted.

The objection to competency is removable in some cases by a release of all liability to the witness. But it is now provided, by 3 & 4 W. 4. c. 42., that whenever a witness is objected to as incompetent on the ground that the verdict would be evidence for or against him, he shall nevertheless be heard; and his name being entered on the back of the record, the verdict so obtained shall never be used as such evidence.

All testimony must be given under a judicial oath, with an exception only in favour of Quakers, which is now extended to criminal as well as civil cases.

Evidence, immediate and mediate. — Besides the exclusion of *witnesses* on the score of competency, large classes of *evidence* are inadmissible. Admissible evidence must be, in general, immediate; that is, it must convey the actual knowledge or belief of the witness. This rule excludes, as a general proposition, all hearsay; that is, all narration of the declarations made by others to the witness. There are, however, several classes of mediate testimony which are admissible. Such are, general reputation in certain cases; and declarations, made by a party to the suit, which contain admissions contrary to his own interest. So, in various cases, letters or entries made in books are admissible, where they contain similar admissions. Upon the same principle, the confession of a prisoner is evidence (if unextorted by fear or hope) in a criminal case. Depositions of a witness now deceased, but who had formerly given evidence on the same dispute, are admissible. Evidence may also be considered as divided into original or best, and secondary evidence. For instance, the reading of a document is better evidence of its contents than statements, either written or oral, respecting them. It is a general rule, that all secondary evidence is excluded, if better evidence (that is, evidence of a class which the law recognizes as better) happen to be attainable. Other exclusive rules rest on grounds of public policy. Thus husband and wife are excluded from giving testimony for or against each other. Communications between an attorney and his client, and, for particular purposes, some other private communications between parties, are in their nature privileged, and cannot be given in evidence.

Examination of Witnesses. — A witness, on being admitted in court, is first subjected to the examination of the party in whose behalf he is called, which is termed the *examination in chief;* and the principal rule to be observed by the party examining is, that leading questions are not to be asked. What are leading questions, it is not always easy to ascertain; but questions to which the answer yes or no would be conclusive of the issue fall undoubtedly within this designation. All questions which suggest an answer may be considered, in one sense, as leading questions; but they are not all equally objectionable. The witness is then cross-examined by the opposite party. The object of cross-examination is twofold: to weaken the evidence given by the witness as to the fact in question, either by eliciting contradictions or new explanatory facts; or, secondly, to invalidate the general credit of the witness. In the latter case, it is a general rule, that a witness may refuse to answer any question, if his answer will expose him to criminal liability; and this, whether immediately or by collateral inference. Whether he can refuse to answer a question tending to disgrace him, without involving him in danger, is a point which has been frequently debated, but which the general practice of our courts seems to settle in the affirmative. The credit of a witness may likewise be impeached by the general evidence of others as to his character. But in this case no evidence can be given of particular facts which militate against his general credit; as this would be in contravention of another rule, that collateral issues — questions of fact unconnected with the subject of dispute — shall not be raised during the course of a trial. Re-examination of a witness by the party who first examined him, must be directed to such new points only as have been raised by the cross-examination. If it is wished to put a question not connected with these points, the proper course is for the counsel to apply to the court to put the question for him.

Evidence, Documentary. — Written instruments, considered as evidence in a court of justice, have been divided into public judicial documents; public non-judicial; private documents; and mixed, which are partly public and partly private. The contents of the record of a court of justice are properly proved by inspection of the record itself; otherwise by *exemplification*, or by *sworn copy*. A copy of a record, under the seal of the Court of Chancery, or of one of the King's other courts, is an exemplification; as are also the records of some inferior tribunals. Office copies are evidence, wherever the law has entrusted a particular officer with the making of them. Sworn copies are copies proved on oath to have been examined with the original. All public documents, whether judicial or non-judicial, which cannot be removed, can be and usually are proved in this manner. But before it can be read, it must be proved that the original came out of the hands of the officer of the court, or from the proper place of deposit. A copy of a copy is in no case admissible.

Mixed documents are of a nature partly public and partly private; such as court-rolls of manors, and corporation books. Examined copies of these are evidence. The books of public companies — as, for instance, the East India Company — are evidence in questions between parties interested in them. Private writings are of two sorts: first, writings to which the person against whom they are offered was party or privy; secondly, writings of third persons. All documents of the first class are, in general, evidence against the party. And an admission under seal (as a deed or bond) is, in general, conclusive evidence against the obligor, or party binding himself; that is, he is *estopped*, or prevented, from offering to rebut it.

A discussion of the rules which govern the admissibility of written instruments not under seal as evidence would occupy far too wide a field for the present purpose. Oral evidence can in no case be received as an equivalent or substitute for an instrument, where a writing is required by law; or to give effect to such an instrument, if defective in any particular required by law; or to vary its terms, if it have been appointed, either by act of law or by compact of the parties, as a memorial of the transaction between them. This rule proceeds on the general principle already adverted to, that where the best evi-

dence can be had secondary testimony shall not be substituted for it. But oral evidence is admissible in various cases, to explain, to restrict, and to defeat instruments, on the ground of fraud or mistake.

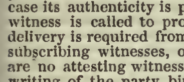
Entries in writing, as well as declarations by third persons, are in general excluded. The cases in which they may be admitted are, either where they serve to explain and accompany material facts; or, in some cases, on a principle of necessity, where the party who made them is supposed to have had peculiar grounds of knowledge as to the fact in dispute. In the first category, as a common instance, we may cite declarations of a trader at the time of his quitting his place of business, which are commonly received in evidence on bankruptcy questions. The second may be instanced by entries of bailiffs or stewards, which are received where the payment of rent is disputed.

Proof of Written Documents.—This is effected either by witnesses, by admission of the adversary, or by enrolment; the latter mode of proof being confined to a few classes of documents by virtue of acts of parliament.

In the first and common mode of proof, the instrument must either be produced, or its absence must be accounted for by loss or destruction (and if either of these negative assertions, as they may be called, cannot be directly proved, evidence of diligent search will be received, and its contents may be proved by counterpart or secondary evidence); or it must be proved to be in possession of the adversary, and that notice was given him to produce it. In the case where the instrument itself is produced, it is either attested or not attested. If the former, the attesting witness must be called; or his absence must be accounted for, and his handwriting proved; or it must appear that the instrument is thirty years old, and has come out of proper custody, in which case its authenticity is presumed. Where a subscribing witness is called to prove a deed, proof of sealing and delivery is required from him; where there are several subscribing witnesses, one is sufficient. Where there are no attesting witnesses to an instrument, the handwriting of the party binding himself is generally sufficient proof. On the proof of handwriting,—a very difficult matter of evidence,—we can only observe, that it is ordinarily proved by the testimony of a witness who has acquired a general knowledge of the party's hand, either by having seen him write (although but once), or by a correspondence with him, or other transactions. It is a general rule, that evidence by comparison of writings is not receivable; and this, although a skilled person (as a clerk from the post office) offer his opinion. (For the mode of taking evidence in courts of equity, *see* CHANCERY.) *Public* documents, when the originals are not procurable, are commonly proved by examined copies.

E'VIL, KING'S. *See* SCROFULA.

E'VOLUTE (Lat. evolvo, *I roll out*), in the theory of curve lines, is a curve from which any given curve may be supposed to be formed by the *evolution* or unlapping of a thread from a surface having the same curvature as the first curve. For example, let B H E be a model of a plane curve made of a solid material having some thickness; and let one end of a thread H E C be fastened to a point B on the edge of the model, and applied along its convexity, so as to coincide with it entirely between B and E, the remaining portion E C of the thread forming a straight line touching the curve at E. Suppose, now, the thread to be gradually unlapped from the curve B E, keeping it always tight: the extremity C will describe another curve, C P D. The curve E H B, by which the curve C P D is generated, is called the *evolute* of C P D; and the curve C P D is called the *involute* of E H B. All curves in which the curvature is neither infinitely great nor infinitely small, may be generated in this way by the evolution of a thread from another curve.



From this mode of generating curve lines it is obvious, first, that P H, the part of the thread disengaged from the arc E H, is a tangent to the evolute at H; second, that P H is a perpendicular to the tangent to the involute C P D at the point P; third, that it is the radius of curvature of C P D at P; fourth, that the point H is the centre of curvature of C P D at P, and that the evolute E H B is the *locus* of the centre of curvature of every point in the involute C P D. Hence the problem to find the evolute of any curve is the same as to find the locus of the points which successively form the loci of its centres of curvature.

Let A Q $= x$, and P Q $= y$; then x and y are the co-ordinates of the point P in the curve C P D, the origin being at A. Let also A K $= v$, and K H $= u$; then v and u are the co-ordinates of H, the centre of curvature of C P D at P; and their values are found from the formulæ,

$$v = x - \frac{dy}{dx} \cdot \frac{dx^2 + dy^2}{d^2 y}; \quad u = y + \frac{dx^2 + dy^2}{d^2 y};$$

in which x is regarded as the independent variable, and y as a function of x, the nature of which is determined by the equation of the curve C P D.

Since the radius of curvature H P is the sum of the arc H E and the straight line C E, it follows that H E is the difference of two straight lines; and since it is possible to form innumerable curves whose radii of curvature are expressible in algebraic terms, therefore corresponding to every such curve there is another curve, namely, its evolute, which can be exactly rectified. The theory of generating curve lines by evolution was proposed by Huygens, before the invention of the differential calculus, and published in his *Horologium Oscillatorium.* His object was to find the evolute of the common cycloid, with a view to the mechanical means of causing clock pendulums to vibrate in cycloidal arcs; for he had already discovered the beautiful property of this curve,—that all vibrations in its arc are synchronous, or performed in equal times, whether the arcs be great or small. *See* CYCLOID.

EVOLU'TION. (Lat. evolvo, *I unfold.*) In Physiology, the theory of generation, in which the germ is held to pre-exist in the parent, and its parts to be unfolded and expanded, but not actually formed, by the procreative acts. The principal and most consistent supporters of this theory maintain that the first created individuals contained the germs of all future possible successors, successively included one within the other; and that generation is merely the act of unfolding, or an evolution of the germ: Swammerdam, Bonnet, Spallanzani, Haller, and Cuvier maintain this theory.

The theory of evolution is opposed to that of epigenesis generation, in which the germ is held to be actually formed as well as expanded by virtue of the procreative powers of the parent. Its chief supporters are Harvey, Caspar Fred. Wolff, Blumenbach, and the professors of the modern German physiological school.

EVOLUTION, in Arithmetic and Algebra, denotes the extraction of roots. (*See* EXTRACTION.) In Geometry, evolution is the opening or unfolding of a curve.

E'VOVÆ. In Music, the vowels used with the ending notes of the ecclesiastical tones: it is a word, for brevity's sake, formed of the six vowels in the words *sæculorum amen*, which are subjoined to the notes in Antiphonaries, &c., to indicate that those are the ending notes.

EXACERBA'TION. (Lat. exacerbo, *I grow violent.*) An increase in the violence of symptoms of disease; as of pain, or especially of fever.

EXÆ'RESIS. (Gr. ἐξαιρέω, *I remove.*) One of the divisions of surgery adopted by old writers, and confined to operations concerned in the removal of parts of the body.

EXALTA'DOS. In Spanish History, the name of the party attached to what has been vulgarly termed the *liberal* system of politics, corresponding to the "extreme gauche" of the French, or Whig-radicals among ourselves.

EXANTHE'MA. (Gr. ἐξανθέω, *I effloresce.*) An eruptive disorder.

EXARCH. (Gr. ἔξαρχος.) The title of the viceroys of the Byzantine emperors in the provinces of Italy and Africa after they had been conquered by Justinian. The exarch of the former province fixed the seat of his government at Ravenna. They were also styled patricians.

EX CA'THEDRA. A Latin phrase; originally applied to decisions rendered by prelates, chiefly popes, from their cathedra or chair: *i. e.* in a solemn judicial manner. Hence applied to every decision pronounced by one in the exercise of his peculiar authority: a professor in his lecture room, a judge from the bench, &c.

E'XCELLENCY. A title of honour in various European states. It was borne, successively, by the Lombard kings; by some emperors of the West; by various minor Italian potentates; and it is now appropriated to persons in the actual execution of certain official services: ministers, some court dignitaries, and ambassadors, but not chargés d'affaires. Governors of English colonies are styled Excellency.

EXCE'NTRIC (Lat. ex, *out*, and centrum, *centre*), in the Ancient Astronomy, is the deferent circle in the circumference of which the centre of the epicycle of a planet is carried forward in its orbit round the earth. It was *excentric* in respect of the earth; that is, though the orbit of a planet was a circle described about the earth, the earth was not placed at the centre of that circle. In modern astronomy, the excentric is the circle which circumscribes the elliptic orbit of a planet. Hence, *Excentric Anomaly* is the arc of the excentric between the perihelion of the orbit and the straight line drawn through the centre of the planet perpendicular to the major axis. *See* ANOMALY.

EXCENTRI'CITY. In Astronomy, the distance of the foci from the centre of the elliptic orbit of a planet or satellite, the semi axis major being regarded as unity; or, it is the ratio of the distance between the focus and centre to the semi axis major. Thus, if a and b denote respectively the semi axes major and minor, and e the excentricity, we have $a e = \sqrt{a^2 - b^2}$. *Excentricity* is thus

to be carefully distinguished from ellipticity, which denotes the ratio of the difference of the two axes to the greater. For the excentricities of the different planets, see PLANET.

EXCEP'TION. In Law, a stop or stay to an action. In common law proceedings, a denial of a matter alleged in bar to an action. In chancery, what is alleged against the sufficiency of an answer.

EXCE'SS, SPHERICAL, in Trigonometry, is the quantity by which the sum of the three angles of a spherical triangle exceeds two right angles.

EXCHA'NGE, in Arithmetic, is the finding the value of one commodity or denomination of money in terms of another. When a unit of each denomination is determined in terms of a common standard, all the operations of this rule are applications of the rule of proportion.

EXCHANGE. In Commerce, a term used to designate that species of mercantile transactions by which the debts due to individuals at a distance from their creditors are paid without the transmission either of money or goods.

Among cities or countries having any considerable intercourse together, the debts mutually due by each other approach, for the most part, near to an equality. There are at all times, for example, a considerable number of persons in London indebted to Hamburgh; but, speaking generally, there are about an equal number of persons in London to whom Hamburgh is indebted; and hence, when A. of London has a payment to make to B. of Hamburgh, he does not remit an equivalent sum of money to the latter; but he goes into the market and buys a bill upon Hamburgh for an equal amount,—that is, he buys an order from C. of London, addressed to his debtor D. of Hamburgh, directing him to pay the amount to A. or his order. A. having indorsed this bill or order, sends it to B., who receives payment from his neighbour D. The convenience of all parties is consulted by a transaction of this sort. The debts due by A. to B., and by D. to C., are extinguished without the intervention of any money. A. of London pays C. of ditto, and D. of Hamburgh pays B. of ditto. The debtor in one place is substituted for the debtor in another; and a postage or two, and the stamp for the bill, form the whole expenses.

A bill of exchange may, therefore, be defined to be an order addressed to some person residing at a distance, directing him to pay a certain specified sum to the person in whose favour the bill is drawn, or his order. In mercantile phraseology, the person who draws a bill is termed the drawer; the person in whose favour it is drawn the remitter; the person on whom it is drawn the drawee, and after he has accepted the acceptor. Those persons into whose hands the bill may have passed previously to its being paid are, from their writing their names on the back, termed indorsers; and the person in whose possession the bill is at any given period is termed the holder or possessor.

The negotiation of inland bills of exchange, or of those drawn in one part of the United Kingdom on another, is almost wholly in the hands of bankers. Many of the banks established in different parts of the country have a direct intercourse with each other, and all of them have correspondents in London. Hence an individual residing in any part of the country who may wish to make a payment in any other part, however distant, may effect his object by applying to the nearest bank. Thus, suppose A. of Penzance has a payment to make to B. of Inverness. To send the money by post would be hazardous; and if there were fractional parts of a pound in the snm, it would hardly be practicable to make use of the post. How then will A. manage? He will pay the sum to a banker in Penzance, and his creditor in Inverness will receive it from a banker there. The transaction is very simple. The Penzance banker instructs his correspondent in London to pay to the London corrrespondent of a banker in Inverness the sum in question, on account of B.; and the Inverness banker being advised in course of post of what has been done, hands over the money to B. The whole charges are limited to a trifling commission and two-pence for postage; so that the affair is transacted in the cheapest as well as in the most commodious possible manner. Bills drawn by the merchant of one country upon another are termed foreign bills of exchange, and it is to their negotiation that the following remarks principally apply.

I. *Par of Exchange.* — The par of the currency of any two countries means, among merchants, the equivalency of a certain amount of the currency of the one in the currency of the other, supposing the currencies of both to be of the precise weight and purity fixed by their respective mints. Thus, according to the mint regulations of Great Britain and France, 1*l.* sterling is equal to 25 fr. 20 cents, which is consequently said to be the par between London and Paris. And the exchange between the two countries is said to be at a par when bills are negotiated on this footing; that is, for example, when a bill for 100*l.* drawn in London is worth 2520 fr. in Paris, and conversely. When 1*l.* in London buys a bill on Paris for more than 25 fr. 20 cents, the exchange is said to be in favour of London, and against Paris; and when, on the other hand, 1*l.* in London will not buy a bill on Paris for 25 fr. 20 cents, the exchange is against London, and in favour of Paris. (See table of the Par of Exchange, at the end of this article.)

II. *Circumstances which determine the Course of Exchange.* — The exchange is affected, or made to diverge from par, by two classes of circumstances. First, by any discrepancy between the actual weight or fineness of the coins, or of the bullion for which the substitutes used in their stead will exchange, and their weight or fineness as fixed by the mint regulations; and, secondly, by any sudden increase or diminution of the bills drawn in one country upon another.

a. It is but seldom that the coins of any country correspond exactly with their mint standard; amd when they diverge from it, an allowance corresponding to the difference between the actual value of the coins and their mint value must be made in determining the real par. Thus, if while the coins of Great Britain corresponded with the mint standard in weight and purity, those of France were either 10 per cent. worse or debased below the standard of her mint, the exchange, it is obvious, would be at real par when it was nominally 10 per cent. against Paris, or when a bill payable in London for 100*l.* was worth in Paris 2772 fr., instead of 2,520 fr. In estimating the *real* course of exchange between any two or more places, it is always necessary to attend carefully to this circumstance: that is, to examine whether their currencies be all of the standard weight and purity; and if not, how much they differ from it. When the coins circulating in a country are either so worn or rubbed as to have sunk considerably below their mint standard, or when paper money is depreciated from excess or want of credit, the exchange is at real par only when it is against such country to the extent to which its coins are worn or its paper depreciated. When this circumstance is taken into account, it will be found that the exchange during the latter years of the war, though apparently very much against this country, was really in our favour. The depression was nominal only; being occasioned by the great depreciation of the paper currency, in which bills were paid. (See art. "Exchange," new edition, *Ency. Britannica.*)

b. Variations in the actual course of exchange, or in the price of bills, arising from circumstances affecting the currency of either of two countries trading together, are *nominal* only; such as are *real* grow out of circumstances affecting their trade.

When two countries trade together, and each buys of the other commodities of precisely the same value, their debts and credits will be equal, and, of course, the real exchange will be at par. The bills drawn by the one will be exactly equivalent to those drawn by the other, and their respective claims will be adjusted without requiring the transfer of bullion or of any other valuable produce; but it very rarely happens that the debts reciprocally due by any two countries are equal. There is almost always a balance owing on the one side or the other; and this balance must affect the exchange. If the debts due by London to Paris exceeded those due by Paris to London, the competition in the London market for bills on Paris would, because of the comparatively great amount of payments our merchants had to make in Paris, be greater than the competition in Paris for bills on London; and consequently the real exchange would be in favour of Paris and against London.

It is plain, however, that all fluctuations of the real exchange must be confined within comparatively narrow limits; and that, though they may be under, they can never exceed, the expense of transmitting bullion from the debtor to the creditor country; for, if they exceeded this amount, it would plainly be more for the debtor's advantage to transmit bullion rather than bills, and the exchange would immediately sink to par.

It is usual to suppose, when the exchange is against a country, that it can only be adjusted by an exportation of bullion; but provided the fall of the exchange be *real*, and not *nominal*, — that is, provided the currency of the country which has the unfavourable exchange be in a sound state, and that it is neither depreciated from excess, nor from the coins being reduced below their mint standard, but that the depression originates in some circumstances affecting the trade of the country, as the occurrence of a bad harvest, the breaking out of a war, &c., — then, in such a case, it may, and most probably will not be necessary to export a single ounce of bullion. Suppose, to illustrate this, that an English merchant has 100*l.* to pay in Petersburgh, and that the real exchange is 3 per cent. against England, or that a bill that cost 103*l.* in London will only fetch 100*l.* in Petersburgh: now, suppose that the cost of transmitting bullion to Petersburgh is also 3 per cent.; the question is, what will the merchant do? If he had no other resource but to send a bill or bullion, it is plain it would be indifferent

to him which he sent. But he is not so restricted. He will compare together the prices of articles in London and Petersburgh; and if he find that there is any exportable article whatever costing in London 100*l.* that will sell in Petersburgh for 100*l.* after paying the expenses of carriage, he will obviously gain 3*l.* by exporting it, rather than transmitting bullion or a bill. The fact is, that a nation might cancel a foreign debt of 10 or 100 millions without sending abroad a single ounce of gold and silver: the latter are never exported, unless when it happens to be more profitable to export them than anything else. They always go abroad to find, and not to lose, their level.

III. A fall of the *nominal* exchange, that is, a fall of the exchange occasioned by the depreciation of the currency, has no influence whatever over trade. When the currency is depreciated, the premium which the exporter of commodities derives from the sale of the bill drawn on his correspondent abroad is countervailed by a precisely equal rise in the price of the commodity occasioned by the depreciation, so that the result is nothing. But it is otherwise when the *real* exchange is depressed, or when the sums payable to the foreigner exceed those receivable from him. In this case, there is no rise of prices, and the depression of the exchange operates as a stimulus to exportation. As soon as the real exchange diverges from par, the mere inspection of a price current is no longer sufficient to regulate the operations of the merchant. If it be unfavourable, the premium which the exporter will receive on the sale of his bill must be included in the estimate of the profit he is likely to derive from the transaction. The greater that premium the less will be the difference of prices necessary to induce him to export; and hence an unfavourable real exchange has an effect exactly the same with what would be produced by granting a bounty on exportation equal to the premium on foreign bills.

But, for the same reason that an unfavourable *real* exchange increases exportation, it proportionally diminishes importation. When the exchange is really unfavourable, the price of commodities imported from abroad must be so much lower than their price at home as not merely to afford, exclusive of expenses, the ordinary profit of stock on their sale, but also to compensate for the premium which the importer must pay for a foreign bill, if he remit one to his correspondent, or for the discount, added to the invoice price, if his correspondent draw upon him. A less quantity of foreign goods will therefore suit our market when the *real* exchange is unfavourable; and fewer payments having to be made abroad, the competition for foreign bills will be diminished, and the *real* exchange rendered proportionally favourable. In the same way, it is easy to see that a favourable *real* exchange must operate as a duty on exportation and as a bounty on importation.

It is thus that fluctuations in the real exchange have a necessary tendency to correct themselves. They can never, for any considerable period, exceed the expense of transmitting bullion from the debtor to the creditor country. But the exchange cannot continue either permanently favourable or unfavourable to this extent. When favourable, it corrects itself by restricting exportation and facilitating importation; and when unfavourable, it produces the same effect by giving an unusual stimulus to exportation, and by throwing obstacles in the way of importation. The *true par* forms the centre of these oscillations; and though the thousand circumstances which are daily and hourly affecting the state of debt and credit prevent the ordinary course of exchange from being almost ever precisely at par, its fluctuations, whether on the one side or the other, are confined within certain limits, and have a constant tendency to disappear.

This natural tendency, which the exchange has to correct itself, is powerfully assisted by the operations of the bill merchants.

England, for example, might owe a large excess of debt to Amsterdam; yet, as the aggregate amount of the debts due by a commercial country is generally balanced by the amount of those which it has to receive, the deficiency of bills on Amsterdam in London would most probably be compensated by a proportional redundancy of those on some other place. Now it is the business of the merchants who deal in bills, in the same way as of those who deal in bullion or any other commodity, to buy them where they are cheapest, and sell them where they are dearest. They would, therefore, buy up the bills drawn by other countries on Amsterdam, and dispose of them in London; and by so doing would prevent any great fall in the price of bills on Amsterdam in those countries in which the supply exceeded the demand, and any great rise in Great Britain and those countries in which the supply happened to be deficient. In the trade between Italy and this country, the bills drawn on Great Britain amount, almost invariably, to a greater sum than those drawn on Italy. The bill merchants, however, by buying up the excess of the Italian bills on London, and selling them in Holland and other countries indebted to England, prevent the real exchange from ever becoming much depressed. (For further information as to the principles involved in this curious and interesting department of commercial and international economy, see the able and excellent tract, entitled *Observations on the Course of Exchange*, by William Blake, Esq., and the art. "Exchange" in the new edition of the *Encyc. Britannica;* and for the practical details connected with the subject, see *Commercial Dictionary*.) We subjoin from the latter a table of the par of exchange between London and some of the principal foreign places for the negotiation of bills of exchange.

Par of Exchange between England and the following Places, — viz. Amsterdam, Hamburgh, Paris, Madrid, Lisbon, Leghorn, Genoa, Naples, and Venice; the same being computed from the intrinsic Value of their principal Coins, by comparing Gold with Gold, and Silver with Silver, according to their Mint Regulations, and to Assays made at the London and Paris Mints.

	Gold.		Silver.				Explanations.
			Old Coinage.		New Coinage.		
	Mint Regulations.	Assays.	Mint Regulations.	Assays.	Mint Regulations.	Assays.	Moneys of Exchange.
Amsterdam, banco	36 8	36 6·8	37 3	37 10·5	35 0	35 6·5	Schillings and pence Flemish per pound sterling. Agio 2 per cent.
Do. current - -	11 4·5	11 3·8	11 8·5	11 11·8	10 14·6	10 17·6	Florins and stivers per pound sterling.
Hamburgh - -	34 3·5	35 1·5	34 1	35 1·3	32 11	32 11·5	Schillings and pence Flemish banco per pound sterling.
Paris - - -	25 20	25 26	24 73	24 91	23 23	23 40	Francs and centimes per pound sterling.
Madrid - -	37·3	37·2	39·2	39·0	41·7	41·5	Pence sterling for the piastre or dollar of exchange.
Lisbon - -	67·4	67·5	60·41	58·33	64·30	62·69	Pence sterling per milree.
Leghorn - -	49·1	49·0	46·46	46·5	49·60	49·5	Pence sterling per pezza of exchange.
Genoa - -	45·5	45·5	46·46	48·9	49.4	52·0	Pence sterling per pezza fuori banco. *
Naples - -	41·22	- -	41·42	- -	43·9	- -	Pence sterling per ducat (new coinage of 1818).
Venice - -	46·3	46·0	47·5	49·9	44·6	46·1	Lire piccole per pound sterling.

* The currency of Genoa has consisted, since 1826, of *Lire Italiane* of exactly the same weight and fineness as francs; so that the par of exchange with Genoa is now the same as with Paris.

EXCHE'QUER CHAMBER, COURT OF, in Law, is constituted by 1 W. 4. c. 70. the proper tribunal for the trial of writs of error from the three superior courts, which before was only partially the case. In this court the writ is tried before the judges, or judges and barons, of the two courts which had not given the former judgment. Error from this court lies in the House of Lords, which is the last and highest appellate tribunal of the country.

EXCHEQUER, COURT OF, in Law, was originally established for the recovery of the king's debts and ordinary revenues of the crown. In its modern shape, it is in fact a combination of eight distinct ancient courts. It acquired concurrent jurisdiction with the other two superior courts in all personal actions (*see* COURTS, SUPERIOR) by the fiction of the complaining party being debtor to the king; a fiction which is now removed. It has exclusive jurisdiction in cases in which the king's revenue is concerned, whether personal actions, or informations filed under the various revenue acts. It has also an equitable jurisdiction; exclusive with respect to matters connected with the revenue, concurrent with the court of chancery in civil suits. It has also the original and proper equitable jurisdiction in cases of tithes. (*See* CHANCERY.) The chief and four puisné or younger judges of the Exchequer are termed Barons.

EXCHEQUER, COURT OF (in Scotland), established on its present footing by 6 Anne, c. 26., should consist of a chief baron and four junior barons (but three only have been commonly appointed). It has a privative jurisdiction as to duties of customs, excise, and other revenues of the crown.

EXCHEQUER BILLS, are bills of credit issued by authority of parliament. They are for various sums, and bear interest (generally from $1\frac{1}{2}d.$ to $2\frac{1}{2}d.$ per diem per 100*l.*) according to the usual rate at the time. The advances of the Bank to Government are made upon exchequer bills; and the daily transactions between the Bank and Govern-

ment are principally carried on through their intervention. Notice of the time at which outstanding exchequer bills are to be paid off is given by public advertisement. Bankers prefer vesting in exchequer bills to any other species of stock, even though the interest be for the most part comparatively low; because the capital may be received at the Treasury at the rate originally paid for it, the holders being exempted from any risk of fluctuation. Exchequer bills were first issued in 1696, and have been annually issued ever since.

Account of the Amount of the Exchequer Bills outstanding in each Year since 1815, and the Rate of Interest payable on such Bills.

Years ended 5 Jan.	Amount outstanding.	Rate of Interest on Exchequer Bills.			Years ended 5 Jan.	Amount outstanding.	Rate of Interest on Exchequer Bills.

EXCISE DUTIES, in Revenue and Finance, are duties imposed on articles produced or manufactured at home, while in the possession of the producers or manufacturers. They were introduced into England by the Long Parliament in 1643, being then laid on the makers and venders of ale, beer, cider, and perry. The royalists soon after followed the example of the republicans; both sides declaring that the excise should be continued no longer than the termination of the war. But it was found too productive a source of revenue to be again relinquished; and when the nation had been accustomed to it for a few years, the parliament declared, in 1649, that the impost of excise was the most easy and indifferent levy that could be laid upon the people. It was placed on a new footing at the Restoration; and notwithstanding Mr. Justice Blackstone says, that "from its first original to the present time, its very name has been odious to the people of England" (*Com.*, book i. c. 8.), it has continued progressively to gain ground; and is at this moment imposed on several important articles, and furnishes nearly a third part of the entire public revenue of the kingdom.

For the more easy levy of the excise duties, England and Wales are divided into about fifty-six collections, some of which are called by the names of particular counties, others by the names of great towns. Where one county is divided into several collections, or where a collection comprises the contiguous parts of several counties, every such collection is subdivided into several districts, within which there is a supervisor; and each district is again subdivided into out-rides and foot-walks, within each of which there is a surveying officer or gauger. Some excise duties, that were justly objected to, have been repealed within these few years; and, with the exception of the duty on glass, which interferes injuriously with the manufacture, we are not sure that there is one of the existing duties that can be fairly objected to on principle, though the rate of duty might, in some instances, be advantageously reduced. It has been said, that the excise duties "greatly raise the cost of subsistence to the labouring classes." But this assertion has really no foundation. In fact, the only excise duty that can be said to fall on a necessary of life is that on soap, which produced in 1838 (in Great Britain) 809,031*l.*; but as the population of Great Britain amounts at present to about 18,000,000, the soap tax cannot, at an average, impose a burden of 11*d.* a year on each individual. If we estimate its annual pressure on a labouring family of five persons at from 2*s.* 6*d.* to 3*s.*, we shall not be within but beyond the mark.

The only taxes, in the various departments of the revenue, that can be truly said to fall on articles necessary to the labourer, are, besides soap, principally those on tea and sugar. We incline to think that the duties on these articles might be very materially reduced without affecting the revenue; but, however that may be, it cannot be truly affirmed that they entail any grievous burden on the labouring classes. The entire nett produce of the excise duties in Great Britain in 1838 amounted to 12,775,955*l.*, of which the duties on spirits and malt, that is, on spirits and beer, produced no less than 8,604,115*l.* In Ireland during the same year, the excise duties amounted to 1,974,566*l.*, of which the spirit and malt duties furnished above four-fifths, or 1,795,165*l.* The rate at which this revenue was collected was nearly 6¼ per cent. in Great Britain, and 9½ per cent. in Ireland. Now, we are bold to say, that no equal amount of revenue was ever raised with so little inconvenience or injury to the contributors. Even though they were not required by the public exigencies, the duties on spirits obstruct a pernicious habit, and should not be given up. They are the best of all possible duties; and the only thing to be attended to in their imposition, is not to carry them to such a height as to defeat their object by encouraging smuggling. We have yet to learn, supposing they are not carried beyond this limit, that a single good objection can be made to these duties.

The obscurity and complexity of the excise laws has been justly complained of. It is needless to say, that they ought to be brief, clear, and level to the apprehension of every one. But, so far from this being the case, they are in most instances lengthened, contradictory, and unintelligible. There were at no distant period some 40 or 50 acts in existence having reference to the glass duties, and at this moment from 25 to 30 have reference to the paper duties, and so for the others. It is, in fact, all but impossible for any one to tell what the law really is on many points; so that the trader is left at the mercy of the officers, and a wide door is opened to favouritism and fraud. This disgraceful state of things might, however, be easily remedied by getting the treasury or the excise to prepare a short abstract of the law as to each duty, drawn up in the clearest and least ambiguous manner possible, and without any of that verbosity, repetition, and technical jargon that infects acts of parliament, and renders them all but incomprehensible to ordinary persons. A manufacturer abiding by this abstract should be held to have abided by the law, and should not be further questioned on the subject. A measure of this sort might be easily carried into effect. It would be an immense improvement, and would go far to obviate the only good objection to the excise duties.

EXCITABI'LITY. A disposition to be affected by exciting causes. It is a term chiefly used in medicine, in reference to that state of system which is more or less susceptible of morbid excitement.

EXCOMMU'NICATION. An ecclesiastical censure, by which a man is cut off from communion with his church. The right possessed by any community of ejecting any person who contravenes the laws by which it is governed is founded on the original principles of society, and is exercised in some shape or other by every sect among Christians. If we suppose, however, one society to be the depositary of all God's covenants and mercies, and to afford the exclusive means of salvation, excommunication will in such case involve eternal perdition, and must be defended on some higher grounds than those of social expediency. An appeal is made to scripture in defence of this practice on the following grounds: — The power of binding and loosing is undoubtedly given to the apostles. St. Paul delivers over to Satan a heretic, or one who troubled the church; the sudden death of Ananias and Sapphira seems to have been inflicted upon them by the apostle himself as a punishment for their crimes; the faithful are charged to keep no company with heretics; Titus is directed by St. Paul to reject such after the first and second admonition. Upon the authority of these passages many Christian churches have assumed the power of excommunication. Protestants, however, do not generally venture to pronounce upon the future condition of a person thus excluded from covenanted benefits; whereas in the forms of excommunication of the Greek and Roman churches, the excommunicated person is solemnly devoted to the devil.

The English church retains a form of excommunication, in cases of adultery, incontinence, heresy, simony, and neglect of public worship, &c.; the practice, however, has long become obsolete. In English law, excommunication was the ordinary mode by which contempt of the ecclesiastical jurisdiction was punished and its process enforced. Forty days after sentence the writ *de excommunicatio capiendo* issued (called also a *significavit*, from the recital of the bishop's certificate with which it commenced), under which the party was apprehended by the sheriff. By stat. 53 G. 3. c. 127. the legal effect of excommunication is abolished, and the writ *de contumace capiendo* substituted for the former one.

EXCORIA'TION. (Lat. excorio, *I remove the skin.*) An abrasion of the cuticle.

EXCRE'TION. (Lat. excerno, *I separate from.*) A substance which is rejected from the body as useless.

EXCU'RRENT. In Botany, a term used in describing the ramification of any body whose axis always remains in the centre; the other parts being regularly disposed around it, as the stem of *Pinus abies.*

EXECU'TION. The carrying into effect of a judgment given in a court of law. Unless execution be taken out within a year and a day after the judgment has been given, the judgment must be revived by writ of scire facias. Execution may be against the person of defendant by imprisonment, which is under a writ of capias ad respondendum. There are also various writs of execution against the goods of a defendant and against his lands. Criminal execution is in the country directed

by the judge of assize who tries the prisoner, and in London by the recorder.

EXECUTION. In the Fine Arts, the mode of performing a work of art, and the dexterity with which it is accomplished.

EXE'CUTIVE. In the theory of Government, that part of the powers of the state which is employed in putting into execution the laws made by the legislative or the decrees of the judicial power. In England, all executive power is supposed to be vested in the king, and in inferior officers by his delegation.

EXE'CUTOR. In Law, an executor is a person appointed by a testator, and whose appointment is confirmed by the proper ecclesiastical court, to execute his will, and to represent him in his personal rights and liabilities. Thus the rights and liabilities of an executor in his representative capacity (the same as those of an administrator), are those of the testator or intestate, arising, — for or against him — either out of contract, or from injury done to his property, real or personal, or from injury done by him to the real or personal property of another; but the liabilities of an executor or administrator do not overreach the property or assets which he has received, or might but for his negligence or default have received, by virtue of his office.

The first and most important duty of executors and administrators is the payment of debts which attach to the property in their hands, in the following order; the reasonable expenses of the funeral, and the necessary expenses of proving the will, or of obtaining letters of administration, being first defrayed.

1st. Debts due to the crown by record or on specialty.

2dly. Debts due to the subject by virtue of the judgment of any court of record.

3dly. Debts acknowledged upon record, as by recognizance.

4thly. Debts due upon specialty, or on account of rent.

5thly. Debts of the crown not upon specialty or record.

6thly. Debts by simple contract.

Creditors of each class are entitled to be paid in full before any thing is allowed to debts of an inferior order; and as between themselves they are paid pro rata as far as the assets will extend. But an executor will be allowed, upon account, any debt that he may have paid without notice of another debt of a higher class; and as between creditors of equal degree, he may, before action brought at law, or decree to account in equity, give preference to any. He may also at any time as against creditors of an equal class retain a debt due to himself.

Next to debts stand, in the first place, specific legacies, *i.e.* gifts of specific parts of personal estate; and in the next place general legacies, that is, gifts of money payable out of the general residue of such estate: what remains after payment of legacies, where there are any, or where there are none after payment of debts, is divisible among the next of kin according to the Statute of Distributions. Specific legacies may be recovered at law; but the rights of general legatees, and of next of kin, are enforcible only in courts of equity, or in the ecclesiastical courts.

Most frequently also claims in the nature of debt or legacy to which the personal estate of testators or intestates is subject are prosecuted in courts of equity; which do not only, like courts of law, take cognizance of each individual right as brought forward, but will take upon themselves the whole administration of the estate, and retain it in their hands for the purpose of doing justice to all claimants.

In so doing courts of equity are bound to follow the legal order of priority above stated, so far at least as the assets are legal; *i.e.* either recoverable in courts of common law, or arising upon trust direct and proper and co-extensive with the legal interest (*vide* TRUST), to which the principle of *æquitas sequitur legem* applies. But where there are assets recoverable only in equity, and arising upon implied or resulting trusts, these are called equitable; and in the application of such assets the rule obtains of equality between all debts, the priority of debts to legacies, and among these of specific to general, being still observed. Where there are both legal and equitable assets, creditors availing themselves of their priority against the legal assets will not be admitted to any participation in the equitable assets till other creditors shall have received out of them the same proportion of their debts as the creditors of a higher degree shall have been already paid out of the legal assets.

By the recent act of the 3 & 4 W. 4. real estate not devised for or charged with the payment of debts is made assets for the payment of all debts, to be administered by courts of equity according to the legal order of priorities; but real estate so devised or charged still remains as before equitable assets. Executors and administrators as such have no concern in either case with the application of real assets.

Many questions arise in regard to legacies, — as to when they are vested, when specific or general, — which it is impossible to notice within the limits of this summary.

EXEGE'SIS. (Gr. ἐξ, and ἡγέομαι, *I lead.*) The term applied most usually to the exposition or interpretation of the Holy Scriptures; it is also used, however, in an unrestricted sense. This department of biblical learning has been most assiduously cultivated in modern times, especially by the Germans, as the writings of Michaelis, Schleussner, Rosenmüller, Gesenius, &c. amply testify.

EXE'RGUE. (Fr.) In Numismatics, the basis or lower limb of a coin or medal, when separated by a line from the rest of the face, which usually contains words giving the date, place, &c. of the coin, or other subsidiary matter. *See* NUMISMATICS.

EXFOLIA'TION. (Lat. exfolio, *I scale off.*) The separation of a piece of dead bone from the living.

EXHALATION. *See* VAPOUR, EVAPORATION.

EXHAU'STION. In Geometry, a method of demonstration employed by the ancient geometers to prove the equality of two magnitudes, by showing that their difference is less than any assignable magnitude. The ancients employed this method in their difficult researches, particularly in the theory of curve lines and surfaces, and in determining the areas and volumes which those surfaces contain. As they admitted no demonstrations but such as are perfectly rigorous, they did not consider curves as polygons of a great number of sides; but in attempting to discover the properties of any curve, they regarded it as the fixed term or limit to which the inscribed and circumscribed polygons continually approach, and approach the nearer as the number of their sides is increased. Thus they *exhausted*, as it were, the space between the polygons and the curve; and hence this method of procedure was called the *method of exhaustion.*

As polygons bounded by straight lines were known figures, their continual approach to the curve gave a more precise idea of its properties in proportion as the difference was diminished; and by following the law of continuity, an exact knowledge of these properties was at length obtained. But when the properties of the curve were thus divined, as it were, it remained to verify them by a *geometrical* demonstration; and this was done by proving that every contrary supposition necessarily leads to a contradiction. This method of demonstration is the *reductio ad absurdum.*

By the method of exhaustion the ancients demonstrated that the areas of circles of different diameters are to each other as the squares of their diameters; that the volumes of spheres are to each other as the cubes of their diameters; that pyramids of the same altitude are in proportion to their bases; that the cone is the third of a cylinder of the same base, &c. In the same manner Archimedes demonstrated that the convex surface of a right cone is equal to the area of the circle whose radius is a mean proportional between the side of the cone and the radius of the base; that the area of a sphere is four times that of one of its great circles; and that the area of any of its zones is equal to the circumference of a great circle multiplied by the height of the zone. The differential calculus of the moderns is only the method of exhaustion of the ancients reduced to a simple and commodious analysis. (See *Maclaurin's Fluxions;* and *Carnot, Métaphysique du Calcul Infinitésimal.*)

E'XHEDRA. (Gr. ἐξ, *out of*, and ἕδρα, *a chair.*) In Ancient Architecture, a small room in the baths and other buildings appropriated for conversation.

EXHIBI'TION. (Lat. exhibeo, *I show.*) A term applied in modern times to the public display of works of art. This word is also used to denote private benefactions instituted for the maintenance of scholars in the universities. *See* BURSARS.

EXHUMA'TION. (Lat. ex, *out of*, and humus, *the ground.*) The act of digging up a body interred in holy ground by the authority of the judge. In France the laws enforce exhumation on proof that any person has been killed in a duel.

E'XIGENT. In Law, a writ which lies when the defendant in an action personal, or in an indictment, cannot be found; and where, in the former case, nothing of his can be found within the county whereby he may be attached or distrained upon. The writ is directed to the sheriff, to proclaim the absent party on five county court days, one after another; and if he do not answer on the fifth, he is outlawed.

E'XILE. (Lat. exsilium, from exsul, *one banished ex solo from the soil of his country.*) In Roman law, the punishment of banishment, or, more strictly speaking, the consequence of the interdiction from the use of fire and water, pronounced in early times as a sentence against great offenders, which compelled them to expatriate themselves. It appears that the direct sentence of exile was not known to ancient Roman jurisprudence. (*Cicero ad Herenn.*) In modern France (before the Revolution), there was a distinction between banishment and exile. The former was a punishment assigned by the law, and producing infamy; the latter a measure of discipline, inflicted by the arbitrary act of the monarch (usually through lettres de cachet). Thus political offenders

were frequently exiled to their estates, to a certain distance from court, &c.

EXISTENCE. *See* PERCEPTION, MATERIALISM.

E'XIT. A word placed in the margin of plays to mark the time at which the player leaves the stage.

EXO'DIUM, in Greek Tragedy, signified the end or denouement of the play; or more properly that portion of it (generally the last act) in which the catastrophe is indicated, or the plot begins to be unravelled.

E'XODUS. *See* PENTATEUCH.

EX OFFI'CIO. (Lat. *by reason of office or duty.*) In general language, every act done by an officer either in prosecution of the general duty of his office, or in executing some special duty imposed by it, is said to be done *ex officio*. But, in more strict phraseology, a proceeding *ex officio* is one taken by an officer of his own will, in execution of what he takes to be the duty of his office; as, where a justice of the peace demands and takes surety of his own discretion, without the request of the injured party. An ex officio information is an information at the suit of the king, filed by the attorney-general, without applying to a court for leave. (*See* INFORMATION.) Ex officio criminal informations are employed in cases of libel, sedition, &c., when officially prosecuted.

EXO'GENOUS. (Gr. ἐξ, and γεινομαι, *I grow.*) A term applied to those plants a transverse slice of whose stem exhibits a central cellular substance or pith, an external cellular and fibrous ring or bark, and an intermediate woody mass, and certain fine lines radiating from the pith to the bark through the wood, and called medullary rays. They are called Exogens, because they add to their wood by successive external additions; and are the same as what are otherwise called Dicotyledons. They constitute one of the primary classes into which the vegetable world is divided, characterized by their leaves being reticulated; their stems having a distinct deposition of bark, wood, and pith; their embryo with two cotyledons; and by their flowers usually formed on a quinary type.

EXO'MPHALOS. (Gr. ἐξ, and ὀμφαλος, *the navel.*) A hernia or rupture at or near the navel.

E'XOPHTHA'LMIA. (Gr. ἐξ, and οφθαλμος, *the eye.*) The protrusion of the eyeball from the orbit. It is usually the consequence of concussions or blows; sometimes it is produced by a tumour in the orbit, which gradually pushes the eyeball out of its socket.

EXOPHY'LLOUS. (Gr. ἐξ, and φυλλον, *a leaf.*) A term invented by Dumortier to be applied to the young leaves of Exogens; since they are said to be always naked, while those of Endogens sheath each other.

EXO'PTILES. (Gr. ἐξ, and πτιλον, *a feather.*) A term invented by M. Lestiboudois for Dicotyledonous plants, because their plumula is naked.

EXORCI'SM. (Gr. ἐξορκίζω, *I bind or charge upon oath.*) The solemn adjuration by which those endowed with certain powers were believed to be able to subject evil spirits to their obedience: more particularly to compel them to leave the bodies of those supposed to be subject to demoniacal possession. The exorcists form one of the minor orders in the church of Rome.

EXO'RDIUM. (Lat. exordior, *I begin an oration.*) In Oratory and Literature, the opening part of an oration; which, according to ancient critics, should be drawn either from the subject itself or from the situation of the speaker; presenting either brief remarks on the general character of the topic on which he is about to deliver himself, or insinuations (according to the advice of Cicero), calculated generally to prejudice the audience in favour of the speaker, and against his adversary.

EXORRHI'ZÆ. (Gr. ἐξ, and ῥιζα, *a root.*) A term invented by Richard to be applied to the embryo of Dicotyledons; inasmuch as their radicle always elongates downwards, directly from the outside of the base of the embryo.

EXOSMO'SE. (Gr. ἐξ, and ωσμος, *impulsion.*) The passage of gases, vapours, or liquids through membranes or porous media from within outwards. Mr. Dutrochet having found that if two fluids of unequal density are separated by an animal or vegetable membrane, the denser will attract the less dense, through the membrane that divides them: this property he called Endosmose when the attraction is from the outside to the inside; and Exosmose when it operates from the inside to the outside of the body acted upon.

EXOSTO'ME. (Gr. ἐξ, and στομα, *a mouth.*) A term invented by Mirbel to denote the passage through the outer integument of an ovule, commonly called the foramen.

EXOSTO'SIS. (Gr. ἐξ, *from*, and οστεον, *a bone.*) In Anatomy, a swelling or tumour of a bone.

EXOSTOSIS. In Botany, a disease to which the roots and stems of trees are subject, when knots or large tumours are formed upon or among the wood. It is caused by a stoppage of growth on the one hand, and an attempt at excessive development on the other. It is from sections of the exostoses of trees that some of the most beautiful wood used by cabinetmakers is obtained.

EXO'STRA. (Gr. ἐξοστρα.) In Ancient Architecture, a machine for representing the interior part of a building as connected with the scene of a theatre.

EXOTERIC. *See* ESOTERIC.

EXOTHE'CIUM. (Gr. ἐξω, *without*, and θηκη, *receptacle.*) That portion of an anther from which the pollen is incorrectly supposed to separate; it is the coating of the anther.

EXO'TIC. (Gr. ἐξωτικος, *foreign.*) Any thing introduced to one country from some other country. In gardening it is sometimes applied to plants which require protection in winter, or to plants in general which are not European.

EXPA'NSION. One of the most common and obvious effects of heat, which expands or enlarges the bulk of all the forms of matter. The expansion of solids by increase of temperature is comparatively small; but it may be rendered sensible by carefully measuring the dimensions of any substance when cold, and again when heated: an iron bar, for example, fitted to a gauge, which shows its length and breadth, will no longer pass through the apertures when heated. Among solids the metals are most expansible and contractile by heat and cold; but they vary much in this respect, as shown in the following table, which exhibits the change of dimensions which several of them undergo when heated, from the freezing to the boiling point of water: —

	Temperature.	
	32°	212°
Platinum - - -	120000	120104
Steel - - -	—	120147
Iron - - -	—	120151
Copper - - -	—	120204
Brass - - -	—	120230
Tin - - -	—	120290
Lead - - -	—	120345
Zinc - - - -	—	120360

The average expansion of glass is very nearly the same as that of platinum. The expansibility of different *liquids* is also very variable; ether, for instance, and alcohol, are more expansile than water, and water more than mercury. The expansibility of mercury is applied to a very useful purpose in the construction of the common thermometer. In general all liquids expand and contract in proportion as they are heated and cooled; but to this law there is a remarkable and anomalous exception in regard to *water*. When a large thermometer tube is filled with water of the temperature of 60°, and placed in a cold situation, or in a freezing mixture of ice and salt, the water goes on shrinking in the tube, till it has attained the temperature of about 40°; and then, instead of continuing to contract till it freezes (as is the case with other liquids), it slowly *expands*, and actually rises in the tube until it congeals. In this case, the expansion above 40° and below 40° seems to be equal; so that water will be of the same bulk at 48° and at 32°. This anomalous expansion of water by cold is productive of some important consequences, considered as a natural operation; for if water, like other fluids, went on increasing in density till it froze, the consequence would be that large bodies of water, instead of being only superficially frozen in winter, would be converted throughout into solid masses of ice. Let us take a fresh water lake as an example. The earth being in winter warmer than the air, the heat is withdrawn from the surface of the water by the cold breezes that blow over it; and the whole body of water has its temperature lowered to 40°, *which is the point of its greatest density*, and a temperature perfectly congenial to fish and most other aquatic animals. The cold now continues to operate upon the surface of the water; but, instead of diminishing its bulk, and therefore rendering it *heavier* than the warmer water beneath, it expands it, and renders it *lighter;* so that under these circumstances a stratum of ice-cold water (at 32°) will be found lying upon the mass of warmer water beneath it (at 40°). The influence of the cold continuing, the surface of the lake will soon freeze, but the water immediately below the superficial covering of ice will be found comparatively warm; and as water is almost a non-conductor of heat, it will be a long time before the ice attains any thickness; and the whole body of water, if of any depth, can never freeze throughout. Indeed, it will be obvious that the retardation of freezing will be proportional to the depth of water which has to be cooled; and hence some very deep basins or lakes are scarcely ever even covered by ice.

As liquids are *enlarged* and consequently rendered specifically lighter by heat, very different effects are produced by applying heat to different parts of the vessels containing them. If the heat be applied to the bottom of the vessel, it is soon heated equally throughout, and made to boil; but if the surface only be heated, it may then be boiled and evaporated, while the lower parts remain quite cold.

Aëriform bodies and vapours are the most expansible

forms of matter, and they present an important peculiarity; for in other substances each individual has its own degree of expansion and contraction, whereas all pure aëriform bodies expand and contract alike; so that if we accurately determine the expansion and contraction of any one of them, that knowledge applies to all the rest. 100 measures of air when heated from the freezing to the boiling point of water, suffer an increase of bulk equal to 37·5 parts; so that 100 cubic feet of air at 32° become dilated to 137½ cubic feet at 212°.

EX PARTE. In Law, of the one part. A commission ex parte in chancery is that which is taken out and executed by one side or party alone, on the other party's neglecting or refusing to join.

EXPECTA'TION OF LIFE. By this term writers on annuities and reversions express the mean duration of human life, after a specified age, according to a given table of mortality. With regard to an individual of a given age, the *expectation of life* is the mean number of future years which individuals of that age, one with another, actually live; those who live longer than that period enjoying as much more life in proportion to their numbers as those who live a shorter time enjoy less. The *expectation of life*, according to this definition, differs altogether from what is called the *probable life*, or the number of years which an individual has an equal chance of surviving. The latter term denotes the period of time at the end of which the probability of being alive is equal to the probability of being dead, or is equal to ½; and this is manifestly the period in which the number of lives in the table, beginning with any given age, is reduced to one half. For example, if in a given table of mortality we find that 1000 individuals are living at the age of 40, and that of these 500 only are living at the age of 63, then the *probable life* of an individual aged 40, according to that table, would be 23 years; that is to say, it is an even wager whether he will be alive or dead at the end of 23 years. The *mean life*, or *expectation of life*, is, however, quite different in principle (though in most tables not very different in amount), and depends on the same mathematical probabilities of living over each future year of life, to the last in the table, as are employed in the calculation of life annuities. It is computed as follows: —

Let the probabilities that a life of a given age will live over

1, 2, 3, 4 .... x years,
be p_1 p_2 p_3 p_4 .... p_x respectively;

then the probability that the life will fail in any given year x, is $p_{x-1} - p_x$.

Now, in computing the portion of existence which an individual may expect to enjoy in respect of any future year x, there are two contingencies to be considered: — 1st, The individual may live over that year, in which case he will enjoy a whole year of life $= 1$. But the probability of this event is p_x; therefore $p_x \times 1 = p_x$ is the portion of time he may at present expect to live in respect of that year. 2d, The individual may die in the course of that year; and as the chances of dying at any particular part of the year are equal, we must suppose him to die at the middle of the year; in this case, therefore, he enjoys half a year of life $= \frac{1}{2}$. But the probability his death will happen in the xth year is $p_{x-1} - p^x$; consequently $\frac{1}{2}\left(p_{x-1} - p^x\right)$ is the portion of time he may hope to live, in respect of that year, on the second contingency.

Adding the two results together, we get $p_x + \frac{1}{2}\left(p_{x-1} - p_x\right) = \frac{1}{2}\left(p_{x-1} + p_x\right)$ for the whole of his expectation of life in respect of the xth year from the present. Substituting successively the numbers 1, 2, 3, &c. for x, in order to get the expectation for each succeeding year till the last age in the table, and denoting the sum of the expectations by E, we find (since $p_0 = 1$)

$$E = \tfrac{1}{2}(1 + p_1 + p_2 + p_3 + \&c.) + \tfrac{1}{2}(p_1 + p_2 + p_3 + \&c.);$$

consequently,

$$E = \tfrac{1}{2} + p_1 + p_2 + p_3 + \&c. \quad \ldots\ldots\ldots\ldots (1)$$

Thus it appears that the true value of the expectation of life is equal to the sum of the probabilities of the life enduring through 1, 2, 3, &c. years to the limiting age of the table of mortality, increased by ½. The labour that would be required to sum this series for every different age is avoided by deducing the expectation of one age from that of the next older, as is usually done in computing annuity tables. Thus, let E_1 denote the expectation of life for an individual one year older than the former, and let the probabilities of his living over 1, 2, 3, &c. years be respectively q_1, q_2, q_3, &c.; then we must have

$$E_1 = \tfrac{1}{2} + q_1 + q_2 + q_3 + \&c. \quad \ldots\ldots\ldots\ldots (2)$$

But from the nature of the probabilities in question,

$$p_2 = p_1 \, q_1$$
$$p_3 = p_1 \, q_2$$
$$p_4 = p_1 \, q_3, \&c.$$

Substituting, therefore, these values in (1), we find

$$E = \tfrac{1}{2} + p_1(1 + q_1 + q_2 + q_3 + \&c.) \quad \ldots\ldots\ldots (3)$$

Whence, on eliminating $q_1 + q_2 + q_3 + \&c.$, from the two equations (2) and (3), we get

$$E - \tfrac{1}{2} = p_1 (E_1 + \tfrac{1}{2}),$$

which is the most convenient form under which the formula can be put for computation.

For the explanation of the manner in which the probabilities p_1 p_2 p_3, &c., are determined from the ordinary tables of mortality, see ANNUITY.

The following table, from Mr. Milne's *Treatise on the Valuation of Annuities and Assurances* (vol. ii. p. 565.) shows the expectation of life at every age, according to the law of mortality at Carlisle: —

Age.	Expectat.	Age.	Expectat.	Age.	Expectat.	Age.	Expectat.
0	38·72	26	37·14	52	19·68	78	6·12
1	44·68	27	36 41	53	18·97	79	5·80
2	47·55	28	35·69	54	18·28	80	5·51
3	49·82	29	35·00	55	17·58	81	5·21
4	50·76	30	34·34	56	16·89	82	4·93
5	51·25	31	33·68	57	16·21	83	4·65
6	51·17	32	33·03	58	15·55	84	4·39
7	50·80	33	32·36	59	14·92	85	4·12
8	50·24	34	31·68	60	14·34	86	3·90
9	49·57	35	31·00	61	13·82	87	3·71

25	37·86	51	20·39	77	6·40	103	0·83

EXPE'CTORANTS. (Lat. expectorare, *to expectorate.*) Medicines which increase the secretion of the tracheal and bronchial mucus. The term *expectoration* is applied to any thing cast off from those vessels or from the cells of the lungs by spitting or coughing.

EXPIA'TION (Lat.) signifies, in its most extended meaning, the act by which a guilty person makes atonement to religion, morals, or society at large, for any crime or fault he may have committed, whatever be its nature or extent. The belief in the efficacy of expiation as a means of compensating for a breach of the moral law, formed an important feature in all the religious creeds with which we are acquainted. In this respect, there is a wonderful coincidence in the mythological system of the ancients, the creed of the Jews, and that of the Christian world. These ceremonies, of course, were very diversified, and varied with the character of every nation and the nature of the crime which it was intended to expiate. Among the Greeks and Romans, expiations were sometimes made for whole cities; and, in the more ancient times, to remove or prevent, or to avert an impending calamity, human victims were immolated. We need here hardly advert to the numerous kinds of expiations in use among the Jews, as the Old Testament is filled with accounts of them; and under the heads ATONEMENT and SACRIFICE, we have defined the great act of expiation by which the guilt of the human race has been atoned for, and God reconciled to man in the Christian dispensation.

EXPILA'TION. In the Roman Law, any injury done to the property of a minor was so designated.

E'XPLETIVE. (Lat. expleo, *I fill up.*) In Composition, chiefly poetical; a word not necessary to the sense, but used merely to fill up the measure of a verse, or give roundness to a period.

EXPLO'SION. (Lat. explosio.) In Natural Philosophy, a sudden and violent expansion of the parts of any object. Explosion differs from expansion in this, that whereas the former is always sudden, and only of momentary duration, the latter is the effect of some gradual and continued power, acting uniformly for some considerable time. See EXPANSION; MATTER, PROPERTIES OF.

EXPO'NENT, in Algebra, is used in various senses; thus we say the *exponent* of a power, the *exponent* of a rank, the *exponent* of a ratio. The exponent of a power is a number or algebraic character expressing the degree or elevation of the power to which the quantity is raised. For example, in the expression a^4, 4 is the exponent, denoting that a is raised to the fourth power. In the expression a^m the exponent m is indeterminate, as it may represent any number whatever. The exponent may also be fractional, in which case it denotes not the power, but the root of the quantity; thus $a^{\frac{1}{3}}$ denotes the

third or cube root of a. Or it may be negative, in which case it denotes the quotient that arises from the division of unit by the quantity raised to that power; for example, a^{-n} is the same thing as $\frac{1}{a^n}$. The earliest writers on algebra denoted the powers of numbers by an abbreviation of the name of the power. Harriot repeated the quantity, and for a^4 wrote $a\,a\,a\,a$; the present convenient system was introduced by Descartes.

The exponent of a rank is the number or place of any term in a series; thus, in the series of uneven numbers, 1, 3, 5, 7, 9, 11, 13, 15, &c., 7 is the exponent of the rank of the term 13, because 13 is the 7th term from the commencement.

The exponent of a geometrical ratio is the quotient that arises from dividing the consequent by the antecedent of the ratio. Thus, in the ratio of 2 to 8, the exponent is $\frac{8}{2}=4$; and in the ratio of 8 to 2, the exponent is $\frac{2}{8}=\frac{1}{4}$ Some mathematicians, however, consider logarithms as the exponents of ratios.

EXPONE'NTIAL. This term is variously applied. The *exponential calculus* is the method of performing algebraic operations on *exponential quantities*, by which is understood quantities raised to powers of which the exponents are indeterminate or variable. *Exponential curve* is a curve defined by an exponential equation, or an equation of the form $y=a^x$, or $y=x^x$. *Exponential equation* is an equation which contains an exponential quantity. Thus $y=x^x$ is an exponential equation. These equations are commonly resolved by means of logarithms. For example, if we had the equation $a^x=b$, in which x is the unknown quantity, by taking the logarithms of both sides we should get $x\log.a=\log.b$ and consequently $x=\frac{\log.b}{\log.a}$. But this method of solution is not always possible; for in the equation $ax+b^{2x}=c$ (and an infinity of others), the value of x can only be found by trial and error. *See* LOGARITHM.

EXPORTA'TION. The act of sending commodities out of one country into another. *See* COMMERCE.

EX POST FACTO. (Lat. literally, *by something done afterwards.*) A punishment inflicted in consequence of a law made with a view to a particular offence already committed is said to be inflicted ex post facto; and the phrase "an ex post facto law," is popularly applied to all laws enacted with a retrospective effect, and with intention to produce that effect, which are justly regarded as tyrannical. That species of laws which the Romans termed *privilegia*, i.e. laws passed in order to impose restrictions on individual citizens, were frequently ex post facto. The English practice of a *bill of pains and penalties* is a species of ex post facto legislation, and was much animadverted on in the debates which took place on the occasion of its adoption against Queen Caroline in 1820.

EXPOSURE OF CHILDREN. *See* FOUNDLINGS.

EXPRE'SSION. (Lat. expressio.) In the Fine Arts, the representation of the various passions of the mind. "Care," says Sir Joshua Reynolds in his Fourth Discourse, "must be taken not to run into particularities. Those expressions alone should be given to the figures which their respective situations generally produce. Nor is this enough; each person should also have that expression which men of his rank generally exhibit. The joy or the grief of a character of dignity is not to be expressed in the same manner as a similar passion in a vulgar face."

E'XTANT. (Lat.) In Literature, something that still exists or is in being. Thus it is said that but part of the writings of Livy, Cicero, Cæsar, &c. are *extant*, the rest being lost.

EXTE'MPORE. (Lat.) A term applied to any thing that is done without premeditation. *See* VOLUNTARY.

EXTE'NT, in Law, is a writ of execution (sometimes called an *extendi facias*), directed to the sheriff, against the body, lands, and goods, or the lands only, of a debtor. Writs of extent were of two kinds — extent *in chief*, and extent *in aid;* to both of which the king was entitled by ancient prerogative, for the purpose of obtaining satisfaction of debts originally due to him, or assigned to the crown. The writ of *extent in chief* is a proceeding by the king for the recovery of his own debt, and in which he is the real plaintiff. The writ of *extent in aid* is also sued out at the instance and for the benefit of the crown against the debtor of a crown debtor; but in this proceeding the king is the nominal plaintiff only. Under this writ the lands, tenements, and possessions, as well as the person of the defendant, may be taken in execution; and if within seven days he do not liquidate the debt, a writ of "venditioni exponas is issued to sell the same;" the crown claiming a priority of satisfaction over every other creditor.

E'XTRACT, or EXTRACTIVE MATTER. The term extract is applied in pharmacy to the brown substance which remains after the evaporation of certain decoctions or infusions of vegetables; thus we have *extract of bark*, *extract of rhubarb*, and so on. These extracts are usually mixtures of gum, starch, sugar, or other soluble matters, along with a certain portion of a peculiar vegetable principle of a brown colour, or which becomes so by exposure to air, and which is soluble in water and in alcohol, but scarcely soluble in ether. It combines with alumina, and is often the basis of brown dyes: it is this principle which chemists call *extractive*, and which is frequently closely allied to various forms of colouring matter.

EXTRACT OF LEAD. A term applied to the impure subacetate of lead obtained by boiling litharge in vinegar. It was first used by a surgeon of the name of Goulard, and hence called *Goulard's extract of lead.*

EXTRA'CTION OF ROOTS. An operation which consists in finding a certain *root* of a number or algebraic quantity; or in finding that number or quantity which, multiplied into itself a certain number of times, will produce the given number or quantity. If we take the series of numbers,

1, 2, 3, 4, 5, 6, 7, 8, 9, 10,

and multiply each into itself, we shall obtain the series of *2d powers* or *squares*,

1, 4, 9, 16, 25, 36, 49, 64, 81, 100;

and multiplying each of these again by its corresponding number in the first column, we get the series of *3d powers* or *cubes*,

1, 8, 27, 64, 125, 216, 343, 512, 729, 1000.

Taking any one of the first series of numbers, for example 7, we see that its 2d power (the 1st power is the number itself), or square, is 49, and its 3d power, or cube, 343. Reciprocally, 7 is said to be the 2d or square root of 49, and the 3d or cube root of 343. It is obvious, on inspecting the above series, that out of all the numbers, consisting of one or two digits, there are only nine which are the squares of other whole numbers; and that of all numbers composed of not more than three digits, that is to say, all numbers up to 999, there are only nine which are the cubes of whole numbers. The roots of all the other whole numbers are not only not integers, but, what is very remarkable, are not expressible by exact fractional numbers, and it is only approximations to their values that can be found.

The rules for extracting the square and cube roots of numbers are to be found in every elementary treatise of arithmetic; but require too many explanations and illustrations to be introduced here to any good purpose. The extraction of the cube root in particular is an intricate and laborious operation; and, since any root of a number can be found immediately from a table of logarithms, it is an operation of very little use. It is to be regretted that so much time as is frequently given to it in our schools should be so unprofitably employed.

The general solution of algebraic equations exceeding the fourth degree, has hitherto resisted the efforts of the greatest mathematicians; but in the case of equations with numerical coefficients (whatever the order of the equation) a value of the unknown quantity, that is, a root of the equation, can always be found by an arithmetical process. A general method of accomplishing this was first given by Vieta; another was proposed by Newton, which has been very commonly employed; but the important discovery by Mr. Horner of Bath of an easy means of performing the arithmetical computations required in Vieta's method has greatly simplified the operation, and in fact rendered the solution of an affected equation of any degree scarcely more laborious than the ordinary process of extracting the cube root. For an account of Horner's method, first published in the *Philosophical Transactions* for 1819, see *Young's Theory of Algebraic Equations;* or the *Companion to the British Almanac* for 1839, in which the reader will find an interesting historical account of the progress of the problem of evolution.

EXTRA'DOS. The exterior curve of an arch. Generally the term is used to denote the upper curve of the *voussoirs*, or stones which immediately form the arch.

EXTRAVAGA'NTES CONSTITUTIONES. In the Canon Law, certain papal constitutions not included in the Corpus Juris Canonici are so called, and comprised in a separate volume. They are those of John XXII. and a few of his successors in the papacy.

EXTRAVASA'TION. (Lat. extra, *external to*, and vas, *a vessel.*) A term applied to fluids when out of their proper receptacles or vessels. Thus when blood is thrown out upon the brain, or into any of the cavities of the body, it is said to be extravasated.

EXTRE'ME. (Lat. extremus.) In Logic, has the same meaning with *term*, when used in reference to a proposition. The subject and predicate are the two extremes of a proposition, the copula being, as it were, placed between them. In speaking of a syllogism, the extremes are understood to mean the extremes or terms of the conclusion.

EXTREME. In Music, a word employed in describing

those intervals in which the diatonic distances are increased or diminished by a chromatic semitone.

EXTREME AND MEAN RATIO. A straight line is said to be divided in extreme and mean ratio when the whole is to the greater part as the greater part to the less; or when the rectangle contained by the whole line and the smaller segment is equal to the square of the greater segment. Euclid shows how a line may be divided in this manner in the 11th prop. of his 2d book; and it is by means of this proposition that he constructs the decagon on a given straight line.

EXTRE′ME U′NCTION. One of the seven sacraments of the Romish church, founded upon the passage in the Epistle of St. James in which he says, "If any be sick among you, let him call upon the elders of the church, and let them pray over him, anointing him with oil in the name of the Lord." (v. 14.) The performance of this ceremony is supposed to purify the soul of the dying person from any sins that he may have committed, and which have not been previously expiated by participation in the other means of grace. The Protestants usually answer the text above cited by continuing the quotation to the next verse, where it is said, "And the prayer of faith shall save the sick, and the Lord shall raise him up;" from which they argue that reference is made to a miraculous gift which was exercised in the Apostles' time, and has no application to our days. With respect to the usage of antiquity, to which the Romanists lay claim, it is answered that the passages to which they refer allude to the ceremony not as a sacrament for the good of the soul, but only as a rite that carried with it health to the body. When the Apostle goes on to say, that the Lord will forgive the sins of the sick man, this evidently supposes him to have a lively faith; and that such faith is the condition of the miraculous cure.

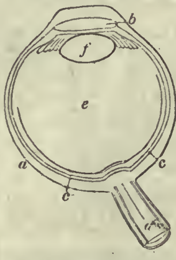
EXTRE′MITIES. (Lat. extremus.) In Painting and Sculpture, the head, the hands, and the feet. In Zoology, the arms and legs, and analogous members in the lower animals.

EXTRO′RSAL. A term used in describing the direction of bodies to denote their being turned from the axis to which they appertain; thus anthers, whose line of dehiscence is towards the petals, are said to be extrorsæ.

EXU′VIÆ. (Lat. *cast clothes.*) This term was applied by the Roman naturalists and poets to the shed skin of the snake: "Positis exuviis novus coluber," says Virgil. And it is extended in modern zoology to the external layer of the integument of every animal, when it is periodically shed entire or in large portions. The films of mucus thrown off from the external surface of most zoophytes and mollusks may be regarded as exuviæ; also those portions of the shell which are deserted and partitioned off by a new-formed plate, as in the *Spondylus varius*, and univalve chambered shells; but the exuvial layers are retained by adhesion to the last secreted portion of the shell. In insects the whole integument is shed generally several times in succession, the last *cadysis* taking place in the transition from the pupa to the imago state. In the *Crustacea* the exuvial shell is commonly cast annually; the cephalo-thorax or carapace cracks longitudinally down the back, and the limbs are withdrawn after successive painful efforts; the lining membrane of the stomach is at the same time shed.

Fishes seem to cast off exuvial layers of mucus only; but in most reptiles the epidermis is periodically moulted, either entire or in large coherent masses. In some species the moulting could only have been detected by careful watching, as the main evidence, the cast skin, is made away with the moment the operation is ended. Mr. Bell thus describes the *cadysis* of the common toad: — "On watching carefully I one day observed a large toad, the skin of which was particularly dry and dull in its colours, with a bright streak down the mesial line of the back; and on examining further, I discovered a corresponding line along the belly. This proved to arise from an entire slit in the old cuticle, which exposed to view the new and brighter skin underneath. Finding therefore what was about to happen, I watched the whole detail of this curious process. I soon observed that the two halves of the skin thus completely divided continued to recede further and further from the centre, and become folded and rugose; and after a short space, by means of the continued twitching of the animal's body, it was brought down in folds on the sides: the hinder leg, first on one side and then on the other, was brought forward under the arm, which was pressed down upon it; and on the hinder limb being withdrawn, its cuticle was left inverted under the arm, and that of the anterior extremity was now loosened, and at length drawn off by the assistance of the mouth. The whole cuticle was thus detached, and was now pushed by the two hands into the mouth in a little ball, and swallowed at a single gulp." The common snake (*Coluber natrix*) when in confinement moults as follows: — The formation of the new cuticle produces a detachment of the old from the subjacent living parts, and the latter then loses part of its transparency and smoothness. As the cuticle is continued over the cornea, the sight of the serpent is dimmed; its motions are also in some degree cramped, and it endeavours to free itself of its incumbrance by rubbing the sides of its mouth against any rough and hard resisting substance. The old cuticle is thereby detached from the circumference of the mouth, and is turned back over the head; and the impediment to vision being thus removed, the snake proceeds with more vigour and rapidity to detach and turn back the cuticle, by repeating the same actions as those with which it commenced the operation; and at length it literally creeps out of its skin, which is left inverted, and more or less entire, according to the degree of the animal's health and vigour at the time of the operation. The rattle-snake is described as actually inverting and drawing off its own skin. After having rubbed back the cuticle from the head, it throws the posterior part of the body in numerous coils around the anterior; one coil is placed in front of the detached part of the integument; and compressing the body strongly, it pushes forward the head and neck, gradually unfolding the coils behind, and stripping off the skin, as it advances forwards. In the warm-blooded classes the periodically moulted feathers of birds, and hairs of various species of Mammalia, may be regarded as exuvial deposits; as also the small scales of the scarf-skin which are incessantly cast off in man.

EYE. In describing the structure of the organ of vision anatomists generally refer to external and internal parts: the former include the eyebrows, or *supercilia*; the eyelashes, or *cilia*; and the eyelids, or *palpebræ*. The cartilaginous edge of the eyelids is called the *tarsus*, in which, and in the inner surface of the eyelids, are small glands which secrete a lubricating serous fluid, called, after their discoverer, the glands of Meibomius. Near the external corner or *canthus* of the eye, and in a depression of the frontal bone, are the lachrymal glands (*glandulæ lachrymales*), which secrete tears; their ducts open on the inner surface of the upper eyelid. The little projection at the inner angle of the eye is called the *lachrymal caruncle*. There are also two small orifices observable at the inner angle, one in the upper and one in the lower eyelid, which are called the *puncta lachrymalia;* they convey the tears by means of two small tubes to the *lachrymal sac*, from whence they pass by the *nasal duct*, which opens under the inferior spongy bone into the nose. The conjunctive membrane of the eye, called also *tunica albuginea*, or white of the eye, is a membrane which lines the inner eyelids and the fore part of the globe of the eye. The internal parts of the eye are, the *sclerotic membrane*, which is the hard outer case of the globe; the *choroid membrane*, which is the interior coat of the sclerotic, beginning around the optic nerve, and proceeding to the margin of the transparent cornea, where it deflects inwardly, forming the *iris*, the posterior surface of which is called the *uvea*, and its central opening the *pupil*, which is muscular, admitting of dilatations and contractions so as to modify the quantity of light admitted into the inner chambers of the eye. The *crystalline lens* is a pellucid body included in a delicate *capsule*, and lodged in a concave depression of the front of the *vitreous humour*, which is a transparent and pellucid pulpy texture, filling the ball of the eye behind the lens, and covered externally by the *hyaloid* or *arachnoid* membrane. The optic nerve enters the back of the eyeball by a perforation in the sclerotic and choroid coats, and is spread upon the posterior and inner surface of the latter, forming a pulpy film or nervous matter called the *retina*. The eye is moved by six appropriate muscles. In the annexed cut, representing a section of the ball of the eye, *a* is the sclerotic membrane or coat, *b* the iris, *c* the retina, *d* the optic nerve, *e* the vitreous humor, and *f* the crystalline lens. *See* VISION.



EYE OF A DOME. In Architecture, the circular aperture in its summit.

EYE OF A VOLUTE. In Architecture, the circle in its centre.

EYE′TEETH. The two upper *cuspidati* are so called in consequence of the length and direction of their fangs, which extend upwards nearly to the orbit of the eye.

EYRE, in Law, signifies the court of justices itinerant. The term is in all probability derived from the Lat. iter, *journey;* as Bracton styles the justices who presided in these courts *justiciarii itinerantes*.

F.

F. The sixth letter of the English and Latin alphabets; a labiodental aspirate, "bearing the same relation to the other labiodental aspirate, V, which the letters called *tenues*, *p*, *k*, *t*, bear to the *mediæ*, *b*, *g*, *d*." It corresponds with the Digamma (quod vide) of the Æolian dialect, to which it is closely related both in form and power; and is susceptible of a few interchanges, chiefly in the Spanish and Latin languages.

F, or FA. In Music, the note on the fourth line in the bass clef generally; but it stands on the third line when the part is Barytone. The ordinary character of the F or bass cleff is 𝄢, which Kepler has much laboured to deduce from F itself.

FA. In Music one of the syllables invented by Guido Aretino to mark the fourth sound of the modern scale of music; rising thus, *ut*, *re*, *mi*, *fa*.

FABACEÆ. (Faba, *a bean*.) An extensive natural order of plants. *See* LEGUMINOSÆ.

FA'BLE. (Lat. fabula.) In Literature, a term applied originally to every fictitious tale; but confined in modern usage to a class of tales, either in prose or verse, which inculcate a moral precept through the medium of a short fictitious story. In the very ancient Indian Fables of Pilpay, the Arabian of Lockman, and the Greek of Æsop, the fictitious personages introduced are chiefly animals, endued for the purpose of the story with human faculties and language; and hence modern fabulists have generally introduced similar agents in the greater number of their fables. In this sense, the fable is synonymous with apologue, and a species of the class allegory. Fables are either in prose or verse; but if the latter, they will not bear with propriety a highly poetical or ornamented character. Herder has divided fables, according to the character of their meaning, into three classes: — 1. Theoretic, intended to form or exercise the understanding; 2. Moral, which contain rules for the regulation of the will; 3. Fables of fate or destiny, in which the narrative contains no maxim of self-conduct, as it merely represents a series of contingencies brought on by necessary connection. But it may be doubtful whether every fable, in the sense in which the name is generally used, does not belong properly to the second class; the instances cited by Herder as appertaining to the first and third were certainly intended by the inventors to bear a moral meaning.

FA'BLIAUX. In French literature, the metrical tales of the Trouvères or early poets of the Langue d'Oil, or dialect of the north of France; composed, for the most part, in the 12th and 13th centuries.

FAÇA'DE. (Fr.) In Architecture, the face or front of any building towards a street, court, garden, or other place; a term, however, more commonly used to signify the principal front.

FACE, in Geometry, denotes in general one of the planes which form the surface of a polyhedron. In Fortification, *face* denotes a line of rampart, or the extent between the outermost points of two adjacent bastions.

FA'CIAL ANGLE, is that angle which is formed by the concurrence of two ideal lines, one of which passes by the hole in the skull termed the meatus auditorius externus to the anterior extremity of the alveolar margin of the upper jaw, while the other extends to the same point from the most prominent part of the forehead.

FA'CIES. (Lat.) In Zoology, a term applied to express the general aspect or external character of an animal, as it appears on a casual or first view; mostly with reference to another to which it bears a superficial resemblance.

In Anatomy, it signifies the anterior part of the skull forming cavities of the orbits, nose, and mouth.

FA'CIES HI'PPOCRA'TICA. The peculiar expression of countenance which indicates the approach of death; it has been accurately described by Hippocrâtes, whence the above common medical term.

FA'CING. In Architecture, that part of the work in a building seen by a spectator; but the term is usually employed to signify a better sort of material which masks an inferior one internally.

FAC SIMILE (Lat. facere, *to make*, and simile, *like*), expressed in French by the words *fais-semblable*, signifies an exact and faithful copy of any writing, engraving, or other work of art.

FA'CTION. (Lat.) In Ancient History, an appellation given to the different troops or companies of combatants in the games of the circus. Of these factions there were four,—the green, blue, red, and white; to which two others were said to have been added by the emperor Domitian, — the purple and the yellow. In the time of Justinian 40,000 persons were killed in a contest between two of these factions; so that they were at last suppressed by universal consent. The term faction is applied also, in a more general sense, to any party in a state which attempts without adequate motives to disturb the public repose, or to assail the measures of government with uncompromising opposition. In the ancient Greek republics, faction was carried to an extent unparalleled in modern times. "We may always observe," says Hume (*Essays*, vol.i. 423.), "where one party (faction) prevailed, whether the nobles or people (for I can see no difference in this respect), that they immediately butchered all of the opposite party that fell into their hands, and banished such as had been so fortunate as to escape their fury. No form of process, no law, no trial, no pardon." The middle ages were distinguished chiefly by two factions, the Guelfs and Guibelins, who long kept Italy in a state of alarm. In the present day, in England, the term *faction* is bandied about between the three great parties of the country, the Whigs, Tories, and Radicals, being applied indiscriminately by the adherents of one party to those of the other. *See* PARTY.

FA'CTOR. (Lat. facio.) In Mercantile Law, a mercantile agent, who is entrusted with the possession of the property which he is commissioned to dispose of. Under the law which obtained previously to the passing of the act 6 G. 4. c 94. it was held that a factor, as such, had authority to sell only, and not to pledge, the goods of his principal; and, consequently, that a party who had made a bonâ fide advance to the factor on the credit of the goods was liable to restore them to the principal without his being bound to repay the advance. By that statute it is enacted, that any person intrusted, for the purpose of consignment or sale, with goods, &c., and in whose name such shall have been shipped, shall be deemed the true owner, so far as to entitle the consignee to a lien thereon in respect of any money or negotiable security advanced by such consignee for the use of the person in whose name such goods, &c. shall have been shipped; provided the consignee has no notice, by bill of lading *or otherwise*, that such party is not the true owner. Various other provisions are added by the same act, to the effect that persons in possession of bills of lading shall be deemed owners, so far as to make valid contracts; that no person can acquire a security upon goods in the hands of an agent for an antecedent debt beyond the amount of the agent's interest in the goods; that persons may contract with known agents in the ordinary course of business, or out of that course, if within the agent's authority; that person may accept and take goods in pledge from known agents; and a right is preserved to the true owner to follow his goods, while in the hands of his agent or the agent's assignee, in case of the bankruptcy of such agent or assignee. A factor has a general lien on goods consigned to him, not only for incidental charges, but as an item of mutual account for the balance due to him, as long as he remains in possession.

In Scotland, the term *factor* is used synonymously with *steward* in England.

FACTOR, in Arithmetic and Algebra, is the name given to each of the quantities which we multiply into one another in order to form (*facere*) a product; that is to say, to the multiplicand and the multiplier. Factors are otherwise called *divisors*, especially in speaking of a number which is regarded as the product of several others.

FA'CTORY. Establishments supplied with machinery for the purpose of carrying on any branch of manufacture, are usually called *factories*. Hence we have woollen, cotton, flax, &c. factories, according to the different branches of industry carried on in each. Factories on an extensive scale are to be found only in countries far advanced in civilization, and where the arts are highly improved. In rude countries, and in the earlier stages of society, manufactures are necessarily carried on upon a small scale, with very imperfect instruments, and little or no division of labour. In factories, on the contrary, the most improved machinery is introduced; every individual has a peculiar task to perform, in the execution of which he cannot fail to acquire the greatest proficiency. We need not, therefore, be surprised to learn that, wherever factories are generally introduced; domestic manufactures are totally superseded, as all classes find it to be more for their advantage to buy the products furnished by the factories than to attempt to supply themselves with similar products by their own labour.

Many complaints have been made as to the injurious influence of factory labour on the health of the labourers, and especially of the young persons, employed in them. This, however, is a subject as to which there has been much misrepresentation. Children, that is, young persons between the ages of nine and fourteen years, as well as adults, are largely employed in factories; and, while the health and morals of the latter are said to suffer severely, the former have been described as being stunted in their growth, and rendered decrepit and miserable for life, by the prolonged confinement, drudgery, and ill treatment to which they are exposed. These representations of the injurious effects of what has been called *white slavery*, were at length embodied in a Report of a Committee of the House of Commons in 1832. We believe, however, that we run little risk in affirming that this report contains more false statements and

exaggerated representations than any other document of the kind ever laid before the legislature. It made a great sensation; and the discussions to which it, or rather the proposal that grew out of it, for limiting factory labour to ten hours a day, gave rise, induced government to appoint a commission to inquire, on the spot, into the actual condition of the labourers, and especially of the children, employed in factories. This commission collected a great deal of valuable and authentic information; and much light has since been thrown on the question of factory labour. It were absurd to pretend, as some have done, that the statements and representations as to its pernicious influence have been proved to be *wholly* destitute of foundation; but they have been shown to be very greatly exaggerated. That great inattention to cleanliness, and some very revolting abuses, have existed in some factories, particularly in those of the smaller class, is quite certain; but the instances of abuse bear but a small proportion to the total number; and, speaking generally, factory work-people, including non-adults, are as healthy and contented as any class of the community obliged to earn their bread in the sweat of their brow.

We do not, however, know that we should object to the total exclusion of children, from nine to thirteen years of age, from factories, provided we had any reasonable security that they would be moderately well attended to and instructed at home. But no such security is to be looked for. The parents of such children frequently want the ability, oftener the opportunity, and sometimes the wish, to keep them at home in any thing like a decent condition; to provide them with instruction, or to impress on them the importance of habits of cleanliness, sobriety, and industry. Were they turned out of the factories, few would either go to the country or to school. Four fifths of them would be thrown loose upon the streets, to acquire a taste for idleness, and to be early initiated in the vicious practices prevalent amongst the dregs of the populace in Manchester, Glasgow, Leeds, and other great towns. Whatever may be the state of society in these towns, we hesitate not to say that *it would have been ten times worse but for the factories.* They have been their best and most important academies. Besides taking the children out of harm's way, they have imbued them with regular, orderly, and industrious habits. Their earnings are considerable, and are a material assistance to their parents; at the same time that they make them perform their tasks with a zeal and alacrity that is rarely manifested by apprentices serving without pay, merely that they may learn some art, trade, or mystery. Many factories have also day schools, or Sunday schools, or both, attached to them, which the children attend. But, independently of this, the training they undergo in factories is of inestimable value, and is not more conducive to their own interests than to those of the public.

Besides supposing that the health of the population is injured by the extension of manufactures, it has been supposed that the extreme subdivision of labour in manufacturing establishments, and the undivided attention which every one employed in them must give to the single operation in which he is engaged, has a most pernicious influence over the mental faculties. The genius of the master is said to be cultivated, but that of the workmen to be condemned to perpetual neglect. "Many mechanical arts," says Dr. Ferguson (*Essay on Civil Society*, p. 303.), "require no capacity; they succeed best under a total suppression of sentiment and reason; as ignorance is the mother of industry as well as of superstition. Reflection and fancy are subject to err; but a habit of moving the hand or the foot is independent of either. Manufactures accordingly prosper most when the head is least consulted, and where the workshop may, without any great effort of imagination, be considered as an engine, the parts of which are men." Similar statements have been made by others. Even Dr. Smith, who has given so beautiful an exposition of the benefits derived from the division of employments, has in this instance concurred with the popular opinion, and has not hesitated to affirm that constant application to one particular occupation in a large manufactory "necessarily renders the workmen as *stupid and ignorant as it is possible to make a human being*." Nothing, however, can be more marvellously incorrect than these representations. Instead of its being true that the workmen employed in manufacturing establishments are less intelligent and acute than those employed in agriculture, the fact is distinctly and completely the reverse. The weavers and other mechanics of Glasgow, Manchester, and Birmingham, possess far more information than is possessed by the agricultural labourers of any county in the empire. And this is really what a less prejudiced inquiry into the subject would have led us to anticipate. The various occupations in which the husbandman has successively to engage, their constant liability to be affected by so variable a power as the weather, and the perpetual change in the appearance of the objects which daily meet his eyes, and with which he is conversant, occupy his attention, and render him a stranger to that ennui and desire for extrinsic and adventitious excitement which must ever be felt by those who are constantly engaged in burnishing the point of a pin, or in performing the same endless routine of precisely similar operations. This want of excitement cannot, however, be so cheaply or effectually gratified in any way as it may be by cultivating, that is, by *stimulating*, the mental powers. Workmen in general have no time for dissipation; and if they had, the wages of labour are too low, and the propensity to save and accumulate too powerful, to allow of any large proportion of them seeking to divert themselves by indulging in riot and excess. They are thus driven to seek for recreation in mental excitement; and their situation affords them every facility for amusing and diverting themselves in this manner. Agricultural labourers, spread over a wide extent of country, are without the means of assembling, except on some rare occasions, for the purpose either of amusement or instruction; but, by working together, those engaged in manufacturing establishments have constant opportunities of discussing all topics of interest and importance. They are thus gradually trained to habits of thinking and reflection; their intellects are sharpened by the collision of conflicting opinions; and a small contribution from each individual enables them to establish lectureships and libraries, and to obtain a large supply of newspapers and periodical publications. But whatever doubt may exist respecting the *cause*, whether it be ascribed to the better elementary instruction of the lower classes in towns and villages, or to the circumstances under which they are placed in after life, there can be none as to the fact that the intelligence of manufacturing workmen has increased according as their numbers have increased, and as their employments have been more and more subdivided. There is not, we apprehend, any real ground for supposing that they were ever less intelligent than the agriculturists; though, whatever may have been the case formerly, none will now venture to affirm that they are inferior to them in mental acquirements, or that they are mere machines without sentiment or reason.

No statutory restrictions respecting the employment of children in the mills and factories of the United Kingdom existed until the year 1802, when an act of parliament was passed (42 Geo. 3.) for the preservation of the health and morals of apprentices and others employed in cotton and other factories; and directing the magistrates to report whether the factories were conducted according to law; and to adopt such sanatory regulations as they might think fit. This act was followed, in 1816, by an act, generally called Sir Robert Peel's Act, imposing various regulations on the employment of children in cotton-mills.

Both of these acts were repealed in 1831 by an act, 1 & 2 Will. 4. c. 39., commonly called Sir John Hobhouse's Act, which provided that in cotton factories, to which alone it related, no child could legally be employed till it had attained the age of 9 years; and that no person under 18 years of age could be suffered to remain in the factories more than 12 hours in one day; and that on Saturdays they should only be employed in the factories for 9 hours.

Sir John Hobhouse's Act was repealed, in 1833, by the act 3 & 4 Will. 4. c. 103., which contains the following provisions, comprehending the whole statutory regulations at present applicable to cotton and other factories in the United Kingdom: —

1. That after the 1st of January, 1834, no person under 18 years of age shall be allowed to work in the night; that is, between half-past 8 P. M. and half-past 5 A. M., in any cotton or other factory in which steam, or water, or any other mechanical power, is or shall be used to propel the machinery, excepting in lace-factories.

2. That no person under 18 shall be employed more than 12 hours in one day, nor more than 69 hours in one week.

3. That there shall be allowed, in the course of every day, not less than $1\frac{1}{2}$ hour for meals to every person restricted to the performance of 12 hours' work.

4. That after the 1st of January, 1834, no child, except in silk mills, shall be employed who shall not be 9 years old.

5. That after the 1st of March, 1834, no child, except in silk-mills, shall be employed in any factory more than 48 hours in any one week, nor more than 9 hours in any day, who shall not be 11 years old; nor after the 1st of March, 1835, who shall not be 12 years old; nor after the 1st of March, 1836, who shall not be 13 years old; and that these hours of work shall not be exceeded, even if the child has worked during the day in more factories than one.

6. That children, and young persons whose hours of work are regulated, shall be entitled to 2 holidays and 8 half-holidays in every year.

7. That children, whose hours of work are restricted to 9 hours a day, are not to be employed without obtaining

a certificate from a physician or surgeon, certifying that they are of the ordinary strength and appearance of children of the age before mentioned, which certificate is to be countersigned by some inspector or justice.

8. That it shall be lawful for his majesty to appoint, during pleasure, 4 persons to be inspectors of factories, with extensive powers as magistrates, to examine the children employed in the factories, and to inquire respecting their condition, employment, and education; and that one of the secretaries of state shall have power, on the application of an inspector, to appoint superintendents to superintend the execution of the act.

9. That those inspectors are to make all rules necessary for the execution of the act, and to enforce the attendance at school, for at least 2 hours daily, out of 6 days in the week, of children employed in factories; from whose weekly wages a deduction, not exceeding 1 penny in every shilling, for schooling, shall be made.

10. That no child shall be employed who shall not, on Monday of every week, give to the factory master a certificate of his or her attendance at school for the previous week.

11. That the interior walls of every mill shall be whitewashed every year.

12. That a copy or abstract of the act shall be hung up in a conspicuous part of every mill.

13. That the inspectors shall regularly, once a year, report their proceedings to one of the secretaries of state.

The act also contains regulations extending the hours of work, where time shall be lost by the want of or an excess of water in mills situated upon a stream of water; respecting the steps to be taken in order to obtain regular certificates of age for the children requiring them; respecting the erection of schools where necessary; and respecting the proceedings to be had before inspectors and magistrates for enforcing the act, and the right to appeal from their decisions.

Account of all the Cotton, Woollen, Worsted, Flax, and Silk Mills or Factories in each County of England and Wales, and in the Kingdom, in the Year 1838; specifying the Amount and Description of the Moving Power, and the Number, Age, and Sex of the Persons employed in the same: compiled from Returns of the Factory Inspectors, printed by Order of the House of Commons in 1839.

Counties.	No. of Mills.		Moving Power.					Actual Power employed.	Persons employed.					
			Steam.		Water.		Total Horse Power.		Under 9 Yrs. of Age.	Ages between 9 and 13.	Ages between 13 and 18.	Ages above 18.	Totals.	
	Working.	Empty.	Engines.	Horse Power.	Wheels.	Horse Power.							Males.	Females.

FA′CULÆ. In Astronomy, certain spots sometimes seen on the sun's disc, which appear brighter than the rest of his surface. These bright spots, and the variable appearances of the solar disc, have given rise to much speculation respecting the constitution of the sun. *See* SUN.

FA′CULTY. (In the Universities.) In the origin of the university of Paris (which is considered as the model of all European institutions in the middle ages) the seven liberal arts (grammar, logic, rhetoric, arithmetic, geometry, astronomy, and music) seem to have been the subjects of academic instruction. These constituted what was afterwards designated the Faculty of Arts. Three other faculties — those of divinity, law, and medicine — were subsequently added. In all these four lectures were given, and degrees conferred by the university. The four faculties were transplanted to Oxford and Cambridge, where they are still retained; although, in point of fact, the faculty of arts is the only one in which substantial instruction is communicated in the academical course. By an anomaly of ancient date, the English universities also give degrees in what is not properly a faculty, but only a branch of one of the faculties, viz. music. On the Continent, the faculty of arts is synonymous with that of philosophy. In England, that of divinity is not wholly distinct from, but superior to, that of arts; degrees in the latter being preliminary qualifications for those in the former.

FA′CULTY, DEAN OF. In Scotland, the elective president of the faculty of advocates, answering to barristers in England.

FAGOTTO. The same as *bassoon*, which see.

FAHLERZ. A mineralogical synonym of grey copper ore.

FA′HLUNITE. A mineral, from *Fahlun*, in Sweden. It is a hydrated silicate of alumina.

FAIE′NCE. (From Faenza, the original place of manufacture.) In the Fine Arts, pottery embellished with painted designs. Raffaelle in his early days is believed to have been much engaged on this department of the art; but the matter is very doubtful. It is certain, however, that many of his designs were transferred to porcelain, which hence obtained the name of Raffaelle's ware; but the date of their execution is posterior to that artist's death.

FAI′NTING. *See* SYNCOPE.

FAINTS. The impure and weak spirit constituting the first and last runnings of the still.

FAIR. (Either from the Latin feriæ or forum.) A meeting held at stated times of the year in particular places, for the purposes of traffic, to which merchants resort with their wares. Fairs, in Christian countries, were usually held on particular festivals; and are so still in England, unless where they have been fixed to particular days in the month by later grants of privileges. By the English law, the king's authority only is supposed to confer the privilege of holding a fair, with the court of pie-powder to determine disputes arising there, which is incident to it. Fairs are considered free, unless toll is due to the owners by special grant, or by custom, which supposes such grant.

FAI′RIES. Imaginary beings, who occupied a distinguished place in the traditional superstitions of the nations of Western Europe, and especially in these islands. Their English name is probably derived from "fair," or has the same etymology with that word; and, although some similarity has been traced between them and the Peris of the Persians (pronounced Feri by the Arabians), it is not probable that the resemblance of name is more than accidental. There is also a distinction between the fairy of our island and the Fata or prophetic sybil of the Italians, from which last the French Fée is derived; although the French, in their romantic mythology, have somewhat mingled the characteristics of the two. The British fairies, also, although they have something in common with the Dwergas or Gnomes of the Scandinavian mythology, are not identical with them; they are in fact peculiar to people of Celtic race, and the notions respecting them prevalent among the Celtic population in Scotland, Wales, and Ireland tally to a remarkable degree. The popular belief, however, was nowhere invested with so poetical a character as in the Lowlands of Scotland, where it forms a main ingredient in the beautiful ballad poetry of the district. The fairies of the Scottish and English mythology are diminutive beings, who render themselves occasionally visible to men, especially in exposed places, on the sides of hills, or in the glades of forests, which it is their custom to frequent. They have also dealings with men, but of an uncertain and unreal character. Their presents are sometimes valuable; but generally accompanied, in that case, with some condition or peculiarity which renders them mischievous: more often they are unsubstantial, and turn into dirt or ashes in the hands of those to whom they have been given. Mortals have been occasionally transported into Fairy-land, and have found that all its apparent splendour was equally delusive. One of the most ordinary employments of fairies, in vulgar superstition, is

that of stealing children at nurse, and substituting their own offspring in place of them, which after a short time perish or are carried away. The popular belief in fairies has been made the subject of poetical amplification in the hands of so many of our greatest writers, from Shakspeare to Scott, that it is not easy to disentangle the embellishments with which it has been invested from the original notions on which they are founded. The Fata of the Italians, who figures in their romantic epics, and from whom the French have made the Fée of their fairy tales, is quite a different personage: a female magician, sometimes benevolent, and sometimes malevolent, partaking herself of the supernatural character, and peculiarly gifted with the spirit of prophecy. Such is the Fata Morgana, to whom the celebrated optical delusion occasionally produced in the Straits of Messina was formerly attributed by popular belief.

FAITH. (Gr. πιστις, Lat. fides.) In Theology. It is observable that the writers of the New Testament employ one and the same word for faith and belief. In most modern languages, the use of two different terms has, perhaps, strengthened the feeling of a difference between the conviction of the heart and that of the understanding: the German, like the Greek, has one only. Faith, in the language of St. Paul, is "the substance of things hoped for, the evidence of things not seen." Perhaps these strong expressions might be more accurately rendered "confidence" in things hoped for (compare 2 Cor. ix. 4. xi. 17.), "conviction" of things not seen. (Heb. xi. 1.) Through this faith, the apostle proceeds to declare, men receive as true things delivered to them on divine authority, to which neither their senses nor their uninstructed reason bear testimony, and endure sufferings and do great actions for God's sake. And without it "it is impossible to please him." Such faith "was imputed" to Abraham "for righteousness" (Rom. iv. 21.); and thus, "being justified by faith, we have peace with God through Jesus Christ." (Rom. v. 1.) It is evident from these as well as many other passages in the Epistles of St. Paul, that this justification is attained only by that faith which obeys the command as well as relies on the promise of God; termed by theologians efficacious or saving faith. Nevertheless, it may be supposed that these passages were misinterpreted by many of those to whom they were addressed, as conveying the doctrine of salvation through the mere act of belief. Perhaps they were among those expressions of St. Paul which, according to St. Peter, those who were unstable "wrested to their own destruction;" since the Apostle James found it necessary to insist so strongly on the inefficacy of faith without works (ii. 17.), or a dead faith (*ib.* 20.), and to assert that "by works a man is justified, and not by faith only" (24.) It is needless to state how much theologians, in every age of the church, have been perplexed by the ethical problem thus presented. Their difficulties may be thought to arise, in great measure, from the inadequacy of our mental powers to separate the naked act of belief, to which, as far as is perceptible to our faculties, no quality of ethical right or wrong can attach, from the moral predispositions which have produced that belief, and the influence on the character which results from it; the whole, perhaps, entering into the Apostolic view of faith. In all ages and churches, there has been a tendency in some to insist exclusively on the doctrine of justification by faith, — a tendency which has sometimes proceeded so far, as in the case of Luther at one period of his life, as to induce them to undervalue or altogether reject the Epistle of St. James; in others, to postpone it to the other great truth of judgment according to works. But the former characteristic has more particularly marked the tenets which are commonly called Calvinistic, in which it is combined with the peculiar doctrine of election; the latter has been apt to prevail in Roman Catholic teaching, and to mingle with what is termed Arminianism in Protestant churches.

FAKI'R, an Arabic word signifying *poor;* applied in some Eastern countries to a sect of enthusiasts, who retire from the world and devote themselves to religious observances. They are chiefly remarkable for their assiduity in "mortifying the flesh," considering no infliction of the body as too severe, provided they can inspire the observer with reverence towards them. There are, however, some classes of Fakirs distinguished for good sense, learning, and piety.

FALCA'TE. (Lat. falx, *a sickle; sickle-shaped.*) In Zoology, when a part is curved with the apex acute.

FA'LCATED. (Lat. falx.) The moon is said to be *falcated* when her illuminated part appears in the form of a crescent or sickle, which happens when she is in the first and fourth quarters.

FA'LCIFORM PROCESS OF THE BRAIN. (Lat. falx.) A process of the *dura mater*, which arises from the *crysta galli* and terminates in the *tentorium*, separating the hemispheres of the brain.

FA'LCO. (Lat. falco, *a falcon.*) The name of a Linnæan genus of Accipitrine Diurnal birds, characterized by a beak crooked, and covered with a cere at the base; head closely invested with feathers. To the short Linnæan phrase descriptive of this group of birds of prey may be added, that the supraciliary arch projects above the eye, giving a bold and threatening physiognomy to these rapacious birds, the majority of which subsist on living prey. The first plumage differs from that of maturity, which is not acquired before the third or fourth year. The female is generally one third larger than the male. The Linnæan genus is now subdivided into the subgenera *Falco*, Bechstein; *Hierofalco*, Cuv.; *Aquila*, Brisson; *Haliætus*, Savigny; *Pandion*, Sav.; *Circætus*, Vieillot; *Harpyia*, Cuv.; *Morphnus*, Cuv.; *Astur*, Bechstein; *Nisus*, Cuv.; *Milvus*, Bechstein; *Pernis*, Cuv.; *Buteo*, Bechstein; *Circus*, Bech; *Gypogeranus*, Illig.

Of these subgenera the first two form what are termed the "noble" birds of prey, and they are the most courageous in proportion to their bulk. This quality is associated with a powerful form of the beak, of which the arch commences from the base, and which is armed with a strong tooth on each side near the apex. Their wings are strong, long, and pointed, the second quill-feather being the longest. It is from this division of falcons that the birds are selected for the sport of falconry.

In the "ignoble" division of the birds of prey, the longest quill-feather of the wing is almost always the fourth, and the first is very short, which gives the wing an appearance of having the extremity obliquely truncated. The bill is not armed with lateral tooth-like processes.

FA'LCONINES, *Falconinæ.* (Lat. falco, *a hawk.*) A subfamily of Accipitrine birds, having the genus *Falco* proper as the type; and characterized by a beak short, hooked from its base, and toothed near the apex; wings long, second quill shortest. It includes the genera *Ferax* and *Falco*. The term *Falconidæ* is used by some ornithologists in a sense as extended as *Diurnæ*, which see.

FA'LCONRY. The origin of this celebrated sport has given occasion to much controversy. It has been said that it was unknown to the Greeks; it is, however, described by Ctesias and Aristotle as practised in their time in India and Thrace. Martial and Apuleius present us with plain indications of the knowledge of this pastime among the Romans. In modern Europe, it appears to have been practised earliest, or at least with most ardour, in Germany: the title of the emperor, Henry the Fowler (A.D. 920), is said to be derived from an anecdote respecting his fondness for it. In the 12th century, it was the favourite sport of nobles and knights throughout Europe; and in that which followed its rules were reduced into a system by the Emperor Frederic II. (Barbarossa), and by Demetrius, physician to the Greek Emperor Palæologus. In that court the grand falconer was an officer of distinction; and the title was borrowed from it by the western sovereigns. According to the opinion of Strutt, the sport was not known so early in England as on the Continent; yet there are traces of it as early as the 8th century. From the commencement of the 17th, we may date its gradual decline. James I., devoted to hunting, was no admirer of falconry, which up to his time had been the favourite royal sport. But its final abandonment, except as the fancy of a few individuals, was owing to the gradual improvement in fire-arms presenting far easier methods of obtaining game. Among the many curious works which exist on this subject, once so universally interesting, may be mentioned the treatise *De la Fauconnesie* of Charles d' Esperon, Paris, 1605; the celebrated *Book of St. Alban's*, by the Prioress Juliani Berners, 1486; *Latham on Falconry*, 1658; *Ray's Idea of Falconry*, published with *Willoughby's Ornithology*. The Emperor Frederic II. (Barbarossa) did not disdain to give the world the results of his experience in the art, in a treatise published in 1596 from his MS., under the title *Reliqua librorum Frederici II. Imp. de arte venandi cum avibus*

FA'LCULA. (Lat. falx, *a sickle.*) In Zoology, a claw is so called when it is compressed, elongate, curved, and sharp-pointed.

FALL. The sea term for the rope of any pulley or system of pulleys. To *fall aboard* signifies to run foul of another vessel.

FA'LLACY (Lat. fallo, *I deceive*), in Logic and Rhetoric, has been defined "any argument, or apparent argument, which professes to be decisive of the matter at issue, while in reality it is not." Fallacies have been divided into those "in dictione," in the words; and "extra dictionem," in the matter. The latter of these it is not the province of logic to discover and refute; they being, strictly, instances in which the conclusion follows from the premises, and which therefore depend on the unsoundness of these premises themselves, which can only be detected by a knowledge of the subject-matter of the argument. Logical fallacies, or fallacies in dictione, are those in which the conclusion appears to follow, but in reality does not, from the premises; and which, consequently, can be detected by one unlearned in the subject-matter of the argument, but acquainted with the

rules of logic. These are subdivided, however, into fallacies purely logical, *i. e.* vicious syllogisms (*see* SYLLOGISM, PARALOGISM), and fallacies semi-logical; those, namely, which arise from the employment of a middle term in argument (*see* SYLLOGISM, PROPOSITION, MIDDLE TERM) ambiguous in sense. In rhetoric, a common set of artifices, by which the mind of the reader or hearer is diverted from the question at issue and fixed on some collateral topic, are termed fallacies; as, where the character of the proposer of a measure is discussed as a reason for or against the measure itself, &c. &c. &c.

FA'LLING HOME. The term applied to the timbers or upper parts of the sides of a ship when they curve inwards. The old ships fell home, or tumbled in (as it is also called), much more than the modern ones, which approach more nearly to being *wall-sided*.

FA'LLING STARS. *See* SHOOTING STARS.

FALL OF MAN. The disobedience of Adam and Eve as related in the book of Genesis, by which sin and death were introduced into the world.

The word *fall* is universally employed in the United States as synonymous with *autumn*.

FALLO'PIAN TUBE. The name given to a canal or tube, discovered by Fallopius, arising at each side of the fundus of the uterus, and terminating in the ovarium.

FA'LLOW. In Agriculture, lands are said to be under fallow when they are without a regular crop of corn or pulse. A naked fallow is one in which the soil remains a whole year without any crop whatever; and a turnip or green crop fallow is one in which the lands after being without a crop from harvest till the beginning of summer, and being properly laboured during that period, are sown with turnips or other similar crops in rows, and the ground cultivated in the intervals. Fallowing was practised by the Romans on all soils whatever, and has been continued through the dark ages, in all the cultivated parts of Europe, so as to have become, till lately, a general habit in the treatment of arable lands. The practice of taking two corn crops, and then allowing the land to rest or lie fallow, was, till the commencement of the present century, prevalent throughout Europe; and it is still a very common practice in most parts of the Continent. It appears to have been first broken through by the Flemings about the end of the 16th century; and subsequently in Britain, with the culture of turnips, above a century and a half later. Fallows, under the most improved systems of agriculture, are no longer had recourse to in the case of free or easily worked soils, where turnip fallows are made, or drill crops of legumes are substituted; but in very strong clays they are still found necessary, and this will probably continue to be the case till by the "frequent drain system," and long-continued culture, the strong clays become friable and fit for the drill husbandry, like the sandy loams and other free soils.

FALSE CADENCE. In Music, one wherein the bass rises a tone or semitone, instead of rising a fourth or falling a fifth.

FALSE KEEL. The timber added below the main keel, both to serve as a defence, and also, by deepening the plane surface, to enable the ship to hold a better wind.

FALSE'TTO. In Music, that part of a person's voice which lies above its natural compass, and is produced to various extents in different subjects, male as well as female. It rarely extends more than four or five notes above the natural voice, and is produced by diminishing the aperture of the throat.

FAMI'LIA. (Lat.) A house or family, being a subdivision of *gens* or clan (*see* GENS). Its members were distinguished by having the last of their three names or the cognomen the same.

FAMI'LIAR, or FAMILIAR SPIRIT; mentioned in the book of Samuel in a passage which has produced much observation from commentators. The genius or δαιμόνιον, which Socrates and some other celebrated ancients were said to have possessed as a companion, was a species of familiar. In modern Europe and Asia, the belief in familiar spirits forms an important feature in the widely spread superstition respecting the magical art. The subject is curiously examined in the article in the *Enc. Metropolitana*.

FA'MILY. In Zoology, the group next in value and comprehensiveness above the genus; existing in fact, though under the name of the genus, in the classification of Linnæus, who indicated the different groups of species therein comprehended by numbers, instead of collective appellations.

Such divisions of the Linnæan genus occur only in those instances in which an unusual number of species presented themselves to the consideration of the clear-sighted Swede. The progress of modern discovery has added so many new forms to the naturalist's catalogue, as to render necessary a corresponding subdivision of most of the Linnæan genera. To these subordinate groups of species distinct names are given, for the sake of convenience; and in order to designate the natural family which these groups compose, the name of the original or typical genus is generally retained, with the addition of the Greek patronymic *idæ* to the genitive case. Thus, *e. g.* the characters of the Linnæan genus *Mus* are applicable to a vast number of Rodents, which scientific precision requires to be arranged in numerous subordinate groups; these are distinguished by appropriate generic names in modern systems, and the term *Muridæ* is applied to the *family* which they collectively compose.

FAN, FANNERS, or FANNING MACHINE. A machine for separating the chaff, husks, dust, or other light matters from seeds which are to be preserved for sowing, or for some other purpose in general or domestic economy. The air is put in motion by a wheel, commonly driven by hand with leaves or fans instead of spokes, directed in a stream against the seeds to be fanned; which seeds are placed in a hopper, so regulated as to proportion their descent through the stream of air to the force of the current created by the fan wheel. Before fanners were invented the process was performed by hand in a manner the reverse of what it is now by machinery; that is, the seeds and refuse to be separated from them were taken up in shovelfulls, and thrown to as great a distance as possible through the calm air; when the full-bodied seeds, being the heaviest, were found at the greatest distance, and the chaff and other matters nearer, according to their degree of lightness. With the progress of the arts a system of screens and sieves was added to the fanning machine; in consequence of which, as it separated the seed from every kind of refuse, it is called a winnowing machine; and in that case, it not only separates the chaff and other light matters generally from the heavy matters, but it parts both according to their bulk and weight; so that the seed comes from the winnowing machine fit for being measured up for the market or store room, and the various kinds of inferior products in a state fit for immediate use.

FANA'TIC. (Lat. fanum, *a temple.*) An enthusiastic and visionary person, who, in matters chiefly relating to religion, disregards reason and scripture, and under the influence of his feelings alone adopts the wildest and most extravagant opinions. The term *fanaticus* was applied anciently to a set of prophetic priests (*Struv. Antiq. Rom.* p. vi. p. 312.), who performed the sacrifices in a wild and extravagant manner; and hence, by an easy transition, has been bestowed in modern times on those who make pretensions to inspiration, or who conduct their worship with extravagance or licentiousness.

FA'NCY. *See* IMAGINATION.

FANDA'NGO. (Spanish.) An air for dancing to, in triple time, and of a quick and lively character. It is the favourite dancing air of the Spaniards, among whom it is of great antiquity. The dancer is usually provided with castanets,—a practice borrowed from the Moors,—which serve to mark the time more distinctly than a stringed instrument alone would do. The Spaniards in dancing to this species of air often carry their gestures beyond the bounds of decency.

FANTA'SIA. (It.) In Music, a species of composition in which the author ties himself to no particular theme, ranging as his fancy leads amidst various airs and movements. Rousseau in his definition of this word confines its meaning to extempore composition, and makes this distinction between the *Capriccio* and the *Fantasia*; namely, that the former is a collection of singular and whimsical ideas strung together by an excited imagination and written down at one's leisure, whilst the latter is an off-hand display of whatever comes across the mind at the instant of execution.

FANTOCCINI. (It. fantoccio, *a puppet.*) Dramatic representations in which puppets are substituted in the scene for human performers.

FARCE. (From the French word, which again is derived from the Italian, and this from the Latin farcire, *to stuff.*) In English Dramatic Composition, a short piece of low comic character. The original term seems, like the Lanx Satura of the Romans, which gave its denomination to the satire, to signify a miscellaneous compound or mixture of different things. In modern languages it has borne various significations. Certain songs which were sung between the prayers on the occasion of religious worship are said to have been denominated Farces in Germany, during the middle ages; whence the word appears to have denoted simply an interlude of any kind. In England, the farce appears to have risen to the dignity of a regular theatrical entertainment about the beginning of the last century; since which time it has formed one of the most popular of our exhibitions, and usually performed by way of contrast, after a tragedy at the national theatres. The farce is restricted to three acts as its limit, but frequently consists only of two or one. Of all the pieces of this class which have successively amused English audiences, none have acquired a permanent literary reputation except those of Foote,—performances in which the licence of the theatre in satirizing living persons was carried to the utmost height. The *Fabulæ Atellanæ* of the Romans, which appears to have been short dramatic entertainments of a miscellaneous character, sometimes pastoral, sometimes tragi-comic, &c.

but not so coarse in plan or diction as the *Mimes* and their *Exodia*, which were satirical dialogues in verse between some set characters or stage-buffoons, appear to have filled in some respects the place of the modern farce. On the French stage the vaudeville answers to the English farce. *See* VAUDEVILLE.

FA'RCY, or FARCIN, is a disease of the horse which affects the lymphatics of the skin, either generally producing a distended appearance of the vessels like moles or buttons, when it is called the bud or button farcy; or locally, when it is chiefly confined to dropsical accumulations in the legs, and is called the water farcy. Both forms of the disease are contagious; and, like the glanders, an allied disease, both are difficult to cure. The button farcy is generally removed by burning off the buttons by caustics or a red-hot iron, and by the exhibition of mercury; and the water farcy by the exhibition of mercury alone. Both diseases are sometimes cured by feeding the animal entirely on green food. See Blaine in *Encyc. of Agr*. 2d edit. page 985.

FARI'NA. (Lat. far, *corn*, of which it is made.) Meal or flour, obtained by grinding and sifting wheat and other seeds; hence the term *farinaceous food*.

FA'RM. In Agriculture, a farm is a portion of land, with suitable buildings, fences, and other arrangements necessary for carrying on the business of farming, which is let to the farmer or occupier for rent. Farming is no doubt coeval with the invention of property in land; because we may suppose that when a proprietor had taken possession of a portion of territorial surface, and called it his own, he would require the assistance of various persons to cultivate it; and these persons he could only remunerate by giving them a share of the produce. Hence the origin of what on the Continent is called the Metayer system, — in which the landlord supplies the farmer or tenant with the soil, buildings, and the whole or a certain portion of the stock; while the latter supplies the labour of cultivation and management, and takes as a remuneration the half, or some other measure of the produce. In process of time, as the tenants or farmers began to acquire capital, they furnished the whole of the live and dead stock, as well as the labour of cultivation and management, and paid the proprietor or landlord a fixed rent in money or produce. To enable the tenant or farmer to do this with the greater security, leases were invented, by which the tenant holding the land for a certain number of years was enabled to lay out money for its improvement at the commencement of his lease, and to receive it back again in the form of increased produce before its termination.

At the commencement of this system of what may be called free farming, all farms were undoubtedly of very limited extent; but with the increase of capital and skill on the part of the farmer they have become greatly enlarged. Much has been written respecting the most profitable size of farms for the public; but this may safely be left to the interest of the parties immediately concerned. Whatever size of farm brings in the highest rent to the landlord will be the best size for the public; because the higher the rent the greater the amount of the produce that must be sent to market to pay it. That there is a natural limit to the size of farms there can be no doubt; but what this is is a different question, and has no connection with the other. It depends on the character of the surface, the kind of farming, and the climate. But though there is a natural limit to the size of farms, and which in any given case can be readily defined, there is no limit to the number of farms that an individual may hold but those of his capital and his skill.

FA'RMERY. The buildings and yards necessary for carrying on the business of a farm. Their situation should be central to the farm lands, in order that the distance from which the crops are brought from the fields to the farmery, and the manure carted from the farmery to the fields, may be reduced to the lowest degree; for when the farm buildings are on one side of the farm lands, it is evident that the cartage to or from the more distant fields must be attended with considerable loss of labour and time. The characteristic yard of the farmery is the rick yard, and the principal feature among the buildings is the barn.

FARMING. The business of farming, or the cultivation of lands held on lease, necessarily varies in different countries and climates; but one point is common to them all, — viz. that no article shall be cultivated which shall not fully remunerate the cultivator or farmer within the limits of his lease. Hence, as few leases in any part of the world exceed twenty years in duration, timber trees are never objects of cultivation by farmers; and it is only in particular cases that orchards and vineyards can be planted by them. As a business, farming may be described as that which under ordinary circumstances yields a lower degree of profit than any other mode in which capital and skill can be employed; but where abundance of capital and extraordinary skill are brought to bear on farming its profits, on an average of a long series of years, may perhaps not be much inferior to those of commerce and manufactures, on the average of a very long period. The great advantages of farming as a pursuit are — 1. That the articles produced, being of the first necessity, there is always a market for them at some price, without the necessity of any or of much exertion on the part of the farmer; 2. The certainty of always having a home and the means of existence on the farm; and 3. The comparative degree of independence which these circumstances are calculated to create in the mind. These advantages, however, depend much on the length of lease, and on the rent being equitable.

FA'RROW. A sow is said to farrow when she brings forth pigs; and the pigs brought forth are called a litter or farrow.

FA'RTHING. A small English copper coin, amounting to one fourth of a penny; it was anciently styled fourthing, as being the fourth of the integer or penny.

FA'RTHINGALE. A name given to the hoop of whalebone used formerly by the ladies of this and other European countries to spread out the petticoat to a wide circumference. It was introduced into England in the reign of Queen Elizabeth, and continued to be used on state occasions down to the commencement of the present century. (See *Strutt's Manners and Customs*.)

FA'SCES. (Lat.) In Ancient History, some of the insignia of authority of the chief magistrates of Rome. They consisted of bundles of wooden rods, each enclosing an iron axe so that its head appeared above; and were used as instruments of punishment, the rods being applied for minor offences, and the axe for capital crimes. They were carried before the magistrates on public occasions by officers called *lictors*, and the number appointed to each varied for the different magistracies. Thus the civic prætors had two, proconsuls and provincial prætors six, the consuls twelve, and dictators twenty-four. The municipal decemvirs also had the privilege of having two fasces carried before them in their own towns.

FA'SCIA. (Lat. *a band*.) In Architecture, a flat member in an entablature or elsewhere, like a flat band or broad fillet. The architrave, when subdivided for instance, has three bands, called fasciæ; of which the lower is called the first fascia, the middle one the second, and the upper one the third. *See* IONIC and the other Orders.

FA'SCIÆ. In Astronomy, bright stripes or belts observed on the discs of some of the planets, particularly Jupiter. The fasciæ or belts of this planet are sometimes broader and sometimes narrower, and alter their situation on the body of the planet, though they always appear parallel to his equator. *See* JUPITER.

FA'SCIÆ. In Anatomy, the tendinous expansions of muscles. The *fascia lata* is a strong tendinous sheath of the muscles of the thigh.

FA'SCICULA'RIA. (Lat. fasciculus, *a bundle*.) A genus of extinct Zoophites, whose calcareous cases are in the form of tubes aggregated together in conical bundles, like those of the organ-pipe coral (*Tubifora*). The *Fascicularia* are abundant in the English coralline crag formation.

FASCI'CULUS. In Botany, a form of inflorescence exactly similar to that called a corymbus, with the exception of the expansion being centrifugal in place of being centripetal.

FASCINA'TION. The fact of being charmed, operated upon, or influenced by the look of certain individuals, generally taken in an evil sense. The word is originally derived from the Greek βασκάινειν (*Theocr.* Idyl VI.), whence the Latin fascinare. *Fascination* is the power supposed to be possessed by certain persons of working mischief to others by means of a glance of the eye. We find it mentioned in Theocritus; and it was so prevalent among the Romans that it was personified as the god Fascinus, the patron of the evil eye. Virgil alludes to it thus: —

> Nescio quis teneros oculus mihi fascinat agnos.
> *Eclog.* 3.

It is to this day a common belief among the vulgar in almost all countries; but probably it is nowhere more generally retained than in Turkey and the kingdom of Naples and Sicily. In the former country, the Mussulmans deem it necessary to have recourse to a variety of amulets and charms, in order to preserve themselves from the evil eye of an enemy, or of an infidel. In Naples, the evil eye and its fascination (known to them by the name of gettatura) are subjects of dread and superstitious precaution among all classes of the people. There is a treatise on fascination by Vairus, prior of a convent at Benevento in that country (1589); another by Frommann (1675).

FA'SCINES (Lat. fascina, *fagot*), in Fortification, are bundles of fagots, twigs, or branches of trees, which, being mixed with earth, are made use of for filling up ditches, forming parapets, &c.

FASCIOLA'RIA. (Lat. fasciola, *a swathing band*.) A genus of Pectinibranchiate Mollusks, dismembered from the rock-shells (*Murices*) of Linnæus on account of the smooth band-like surface of their windings, which have

not any "varices;" and distinguished from the species of *Fusus* in having plaits on the columella, which are oblique, and consequently spiral.

FA'SHION. (Fr. façon; originally from the Lat. facere, *to make* or *form.*) A term used to signify the prevailing mode or taste in any country, the only recognized quality which it possesses being mutability. It may safely be averred that in proportion to the influence which fashion exercises in any country may its claim to civilization be vindicated, nothing being so characteristic of a rude and barbarous state of existence as a rigid adherence to the customs of antiquity. The term *fashion* has generally been considered as applicable chiefly to the adornment of the person, in conformity with the prevailing taste as introduced by some individual of consideration in society; but it has a much wider signification, being applied to the most trivial kind of conventional usages, a disregard or ignorance of which is sufficient in the eyes of the votaries of this tyrannical goddess to banish the offender beyond the pale of civilized society. The remark which Horace makes on the introduction, disuse, and revival of language is so applicable to the term in question, that we cannot forbear quoting it in this place:—

> Multa renascentur, quæ jam cecidere, cadentque
> Quæ nunc sunt in honore vocabula, si volet usus,
> Quem penes arbitrium est, et jus, et norma loquendi
> *Ars Poetica*, v. 70.

FA'SSITE. In Mineralogy, a variety of *augite* from Fassa in the Tyrol.

FA'STI. In Ancient History, the records of the Roman state, in which all public matters, military and civil, were registered by the high priest, according to the days on which they took place. The *Fasti* of Ovid is a poem giving an account of the Roman year, and the ceremonies attached to the different days, with their historical or mythological origin. The first six books, containing the first six months of the year, beginning with January, have come down to us; the rest are lost.

FASTI'GIUM. In Architecture, the same as PEDIMENT, which see.

FA'STING. In a theological sense, the abstaining from food as a religious observance. This practice is recommended in the New Testament by the example of the Apostles and early Christians, who are frequently represented as fasting, especially on solemn occasions, such as when Paul and Barnabas are sent forth by the Apostles to preach to the Gentiles. At the same time it must be observed, that during our Saviour's lifetime his disciples were notorious among the Jews for not fasting, as was the common religious practice of the day: from which we must not suppose that Christ did not appoint stated days or periods of fasting, such as among Christians in later times, as well as among the Jews then, have generally degenerated into heartless ceremonial observances, but left such exercises rather to the judgment and feelings of his disciples to be made by them part of their own private devotions. The observances, however, of stated fast days prevailed very early and universally in the church; and the Church of England has not hesitated, accordingly, to point out the practice of early antiquity as a guide to its children in this matter.

In the Romish church, Wednesday and Friday are observed as fasts throughout the year, those being the days on which our Lord was betrayed and crucified respectively. There are a considerable number of fast days that occur also in the course of the year; and the whole period of Lent is held as a term of abstinence, in which the stated fast days that occur are observed with especial rigour (in imitation of our Lord's forty days' fast in the wilderness). These were periods of real abstinence in the primitive church; but the little that was eaten does not appear to have been limited in early times, either in kind or quantity, by any positive precept. Fasting was practised differently by churches and individuals.

The objection then that is brought against the Romish church in this particular is, first, that it commands and enforces that which was originally left to the discretion of Christians; and secondly, that by so doing, and by multiplying the occasions on which such abstinence is enjoined, it causes the practice to be looked upon as a work meritorious in itself and efficient for the expiation of sins, which was never intended to serve any other use than that of a means towards attaining a godly frame of mind.

FA'TALISM. The belief in an overruling fate or destiny which annihilates free will and controls all human actions. For the philosophical doctrine of fatalism, see NECESSITY; for those religious opinions which have assumed a similar character, ELECTION, PREDESTINATION.

FATA MORGA'NA (called also *Castles of the Fairy Morgana*, the spectacle being supposed to be under the influence of the Queen of the Fairies, the *Morgan la Fay* of popular legends). A remarkable phenomenon of *mirage* or unusual refraction, mentioned by different authors and travellers as seen in the straits of Messina, especially in the vicinity of Reggio; and which consists in the appearance in the air, over the surface of the sea, of multiplied images of the objects on the surrounding coasts. It is thus described by Minasi:—"A spectator on an eminence in the city of Reggio, with his back to the sun and his face to the sea, and when the rising sun shines from that point whence the incident rays form an angle of about 45° on the sea of Reggio, sees upon the water numberless series of pilasters, arches, castles, well delineated, regular columns, lofty towers, superb palaces with balconies and windows, villages and trees, plains with herds and flocks, armies of men on foot and horseback, all passing rapidly in succession on the surface of the sea." There can be little doubt that this description, which has been frequently copied, and even admitted into treatises on optics, has received considerable embellishment from the aid of the imagination. Captain Smyth, in his excellent work on Sicily, observes, "I never met with a Sicilian who had *actually seen* any thing more than the loom or 'mirage' consequent on a peculiar state of the atmosphere; but which, I must say, I have here observed many times to be unusually strong." (*Memoir descriptive of the Resources, Inhabitants, and Hydrography of Sicily and its Islands*, p. 109.) See MIRAGE.

FATE. *See* DESTINY, NECESSITY.

FATES. (Lat. fatum, *that which is spoken.*) In Mythology, the three sister goddesses named Clotho (Spinster), Lachesis (Allotter), and Atropos (Unchangeable), whose office it was to spin the destinies of men, and break the threads when their appointed hours of death came. They were also called Parcæ by the Latins. Their Greek name was Μοῖραι, *i. e.* "the Dispensers."

FATHERS OF THE CHURCH. The early Christian writers whose works have thrown light upon the history, doctrines, and observances of the primitive church, and who are thereby entitled to be looked up to by us to a certain extent as guides and instructors. The period to which the list may be extended is, of course, arbitrary. St. Bernard in the 12th century is generally styled the last of the Fathers. The writers of the 1st century, or who were cotemporary with the first disciples, are distinguished by the term Apostolic Fathers. The general character of the writings of these celebrated men, their trustworthiness as witnesses, their authority as judges in matters of doctrine and discipline, and the utility of studying their works, have been, unfortunately, discussed by divines of different parties with far more of prejudice and the spirit of system than the love of truth. It has been sometimes the fashion to exalt and sometimes to depreciate them: seldom have they been used by learned men of any church for the simple and serious purposes of edification. A voluminous controversy was carried on upon this subject between some Protestants, chiefly of the Calvinist churches, who attacked the Fathers, and others, both Protestant and Catholic, who defended them, towards the end of the 17th century. On the former side, two works of some notoriety were produced,—*Daillé's Treatise on the Use of the Fathers*; and *Barbeyrac, Morale des Pères de l'Eglise*. Among many answers, may be cited that of Cellier to Barbeyrac, 1718. In England, Burnet, Hill, Peter Allix, Reeves (*Apologies of the Early Fathers, with Dissertations*, 1709), took part in it. The Benedictines of Paris, in the 17th century, published valuable editions of the principal Fathers, both Greek and Latin. Nourry, a learned member of that order, published an *Apparatus* to Despont's great collection, the *Bibliotheca Patrum*, in which much information is collected. Of late years Mr. Collinson, by his *Bampton Lectures* (1817), raised anew a spirit of controversy on the subject. At Oxford and at Paris, new editions of an extensive and valuable character of the Fathers are now in progress.

FA'THOM. An English measure of length, equal to two yards, or six feet.

FAT OF ANIMALS. A concrete oil contained in the cellular membrane of animals; it is generally white or yellowish, with little smell or taste, and varies in consistency according to the relative quantities of *stearine* and *elaine* which it contains. The ultimate elements of animal fat are the same as those of vegetable oils: according to the analysis of Chevreul, 100 parts of human fat are composed of 79·0 carbon, 11·4 hydrogen, and 9·6 oxygen. Hog's lard and mutton suet are very similarly constituted.

FA'TTENING DOMESTIC ANIMALS. The difference between feeding and fattening, as far as respects domestic animals, consists in this, that the object of the former is to maintain the animal in a state of health and vigour for the purpose of facilitating its growth to maturity, or if mature keeping it in good working condition; while the object of the latter is to accumulate on the animal more flesh and fat than is sufficient for either of these purposes, and in general as much as possible, so as to increase the bulk and weight of the flesh and fat in proportion to the size of the bone. Till within these few years, the means used by all fatteners of domestic animals, whether quadrupeds or poultry, were preventing the animals from taking exercise, and gorging them with food. The excessive fat produced by these means, more especially in sheep and swine, was found to be both disagreeable and unwholesome; and accordingly the most

approved system of fattening animals of every description, at the present day, consists in not merely supplying them with abundance of food, but also of the means of taking exercise. Hence the farmers in the most enlightened districts, such as Berwickshire, East Lothian, &c., instead of tying up their fattening cattle in stables like horses, and placing their food before them, put two or three together in small yards with sheds attached, in which they can run about, eat when they choose, and take shelter from the rain, the cold, or the sun at pleasure under the open shed. Swine are treated in the same manner, and also spring lambs that are fattened for the market. Poultry are no longer kept in coops and crammed, or rabbits in hutches; but the former are allowed to take exercise in fields sown with various herbs, and the latter are kept in a species of artificial warren, where they can take exercise by burrowing.

FAU'CES. (Plural of faux.) The posterior part of the mouth, terminated by the *pharynx* and *larynx*.

FAULT. In Mining and Geology, a dislocation of strata, whether from a break or slip, or the introduction of some extraneous mass.

FAUNA. The animals peculiar to a country constitute its *fauna*. The term is derived from the Fauni or *rural deities* of Roman mythology.

FAU'NUS. An Italian rural deity resembling the Grecian Pan, and, like him, endued with the gift of prophecy. Mention is sometimes made of several Fauni, who were represented, like the satyrs, with the horns and feet of goats. There was an annual festival instituted to their honour, called *Faunalia*.

FAUSSE-BRAYE. In Fortification, a low rampart going quite round the body of the place, the height being about 3 feet above the level ground.

FAUX. The orifice of the tube of the corolla, the tube being formed by the confluence of the petals.

FE'ALTY. In Feudal Law, the oath of fidelity (Fr. féauté) taken by every tenant on admission to be true to his superior lord. General fealty is that due from the subject to the prince; special fealty from tenant to mesne lord. Fealty is said to differ from homage in being due to every new lord. The oath, as administered in England, was fixed by stat. 17 E. 2. c. 2.; but it has long been obsolete, although, in copyhold tenements, the memory of it is still preserved by the customary entry of respite of fealty on the admission of a new tenant.

FEASTS, or FESTIVALS, are days set apart by the church, either for the grateful celebration of the most remarkable events connected with the scheme of redemption, or upon which to commemorate the actions and sufferings of such persons as have been most instrumental in carrying forward the designs of God for the salvation of mankind. This was a practice of the primitive church; but in process of time (as early as the 4th century) the great number of names which had been introduced into the calendar, and the many corruptions which the honour paid to their memory had engendered, rendered its observation both burdensome and superstitious. Accordingly at the Reformation the Protestants directed their attention to the retrenchment and purification of these ceremonies. The English church retains the festivals of the nativity, circumcision, manifestation, the death and resurrection and ascension of Christ, the purification of the Virgin and the annunciation (or Lady-day), Whit Sunday in honour of the Holy Spirit, and Trinity Sunday. Besides these the most remarkable of the Apostles and the Evangelists are commemorated on their respective days; and one day is set apart for the remembrance of all the saints. From this calendar, therefore, the names of the martyrs and saints of later ages are excluded (with which the Romish calendar is so crowded), partly from the uncertainty which hangs over the stories of many of them, and partly also in order to cut away what would otherwise have furnished a dangerous precedent. Festivals are either moveable or immoveable; the former depending upon Easter, the latter being fixed to certain days of their respective months.

FE'ATHER-EDGED. In Architecture, a term applied to a board whose section is triangular, or rather trapezoidal, one edge being very thin.

FEA'THERS. The term, in Zoology, is restricted to those productions of the dermal system which form the most exterior covering of birds, and which consist of the following parts, viz. a quill (*calamus*), a shaft (*rhachis*), and vanes (*pogonium externum et internum*).

The quill is that part of a feather by which it is attached to the skin; it is nearly cylindrical in form, hollow, and semitransparent, possessing in an eminent degree the opposite qualities of strength and lightness. The end which is implanted in the skin is more or less obtuse, and is pierced by an orifice called the lower umbilicus. At the opposite end, where it is continued into the shaft, and just at the meeting of the two lateral vanes, there is another orifice, called the upper umbilicus. The cavity of the quill contains an imbricated series of conical capsules, united together by a central pedicle, forming the membranous remains of the original formative pulp.

The shaft is quadrilateral, with a smooth convex surface, and an opposite concave surface traversed by a longitudinal impression continued from the upper umbilicus. It is covered by an outer layer of firm horny material like that of which the quill is formed, and this incloses a soft elastic substance called the *pith*.

The vane consists of *barbs* and *barbules*.

The barbs are attached to the sides of the shaft, and consist of narrow elongated plates, arranged with their flat sides towards each other, and their margins in the direction of the external and internal sides of the feather. By this disposition they offer much resistance to being bent out of their plane, though readily yielding to any force acting upon them in the line of the stem.

The barbules are minute and often microscopic processes, given off from either side of the barbs, and arranged in a single series, just as the barbs are placed with reference to the shaft. In true feathers, they are short, stiff, and curved in opposite directions on opposite sides of the barb; and the concavities of one series of barbules interlock with those of the adjoining barbs, whereby the whole vane presents a continuous and resisting surface, as in the quill-feathers of most birds. When the barbules are long and disjoined, the feather is termed a plume; in the long dorsal plumes of the peacock, the barbules themselves are ciliated.

In a few instances, as the apteryx and ostrich, the feathers are simple. In most birds each feather is complicated by a part termed the accessory plume. This is usually a small downy tuft; but it varies as to its size both in different species, and even in the feathers of different parts of the body of the same bird. In the body-feathers of the hawks, grouse, ducks, gulls, &c., the accessory plume is generally well developed, and acquires in some species a size equal to that of the feather from which it is produced. In the emeu this is the case with the whole plumage, and the quill of each feather supports two shafts. In the cassowary there are two accessory plumes, one of which is equal to the size of the original feather, the other is much smaller.

Feathers vary in form, size, and function, in different parts of the bird, and have accordingly received distinct names in ornithological science. Thus the feathers which surround the external opening of the ear, and which serve to augment the intensity of sound, are termed the *auriculars*. Those which lie above the scapula and humerus are called the *scapulars*. The small feathers which are arranged in imbricated rows upon the bones of the antibrachium are called the lesser coverts (*tectrices primæ*); those which line the under or inner side of the wings are the under coverts. The feathers which lie immediately over the quill-feathers are the greater coverts (*tectrices secundæ*). The largest quill-feathers of the wing, which arise from the bones corresponding with those of the hand, are termed primaries (*remiges primores*); those which rise from the ulna, towards its distal end, are the secondaries (*remiges secondariæ*); those which are attached to its proximal extremity are the tertiaries (*remiges tertiariæ*, seu *parapterum*). The quill-feathers which grow from the phalanx commonly called *thumb* form what is termed the bastard wing (*alula spuria*). The quill-feathers which are implanted upon the os coccygis are called *rectrices*.

The development of feathers is always preceded by that of down, which constitutes the first covering of young birds. Each down-fasicle consists of a small quill, supporting a bunch of equal-sized finely-ciliated filaments. The down-fascicles are succeeded by the feathers, which they guide, as it were, through the skin; and the feathers of each succeeding plumage serve, during the moult, as the *gubernacula* of those which follow.

The mechanism concerned in the formation of a feather is, as might be expected, of a very complicated character. It consists of vascular parts which secrete the material, and of moulds or capsules, in which the fluid material is thrown into the proper form; the whole is inclosed in an outer sheath, which is protruded with the new-formed feather from the skin, and which becoming dry and friable from contact with the atmosphere, crumbles away, and leaves the feather free to unfold its beautiful and complicated structure.

Every feather, the eloquent Paley justly observes, is a mechanical wonder: "their disposition all inclined backward, the down about the stem, the overlapping of their tips, their different configuration in different parts, not to mention the variety of their colours, constitute a vestment for the body so beautiful, and so appropriate to the life which the animal is to lead, as that I think we should have had no conception of any thing equally perfect if we had never seen it, or can now imagine any thing more so." For the laws which regulate the varieties and changes of plumage, see INDUMENTUM.

FE'BRUARY. (Lat. februo, *I purify*, because in that month funeral lustrations were performed at Rome.) The 2d month of the year, containing 28 days in common years, and 29 in leap years, the intercalary day being given to it as the shortest month.

FE'CIALS, or FETIALS. The Roman heralds, whose peculiar office it was to declare war and conclude peace. The former office they performed with the following ceremonies:—They were first sent to demand redress; and if it was not given within thirty-three days, they returned to the confines of the hostile state and threw a bloody spear into them, having proclaimed war according to a given formula before not less than three adult witnesses. The fecial, who took the oath in the name of the Roman people in concluding a treaty of peace, was called *Pater Patratus*. The college of Fecials was instituted by Numa, and is supposed to have been borrowed from the Greeks. They were probably twenty in number.

FE'CULA, or FÆCULA. (Lat. dim. of fæx, *a sediment.*) When certain vegetable products are bruised and mixed with water, the pulverulent matter which subsides is called the *fecula* or *fæces*; it is commonly of a starchy nature, hence starch is often called *fecula.*

FE'DERAL GOVERNMENT. (Lat. fœdus, *a league or treaty.*) A government formed by the union of several sovereign states, each surrendering a portion of its power to the central authority. But the amount of the power thus surrendered varies in different federations. Thus the government of the German empire as it existed before the French revolution, and that of the United Provinces of the Netherlands, were both termed federal; and the Swiss cantons, under the present Swiss constitution, have retained more of their individual sovereignty, both as to foreign relations and as to domestic arrangements, than those of the United States of America, each being at liberty, in some cases, to make treaties with foreign powers, and also having almost unlimited power to modify its own institutions; while the latter states have transferred the whole of their foreign affairs to the general government, and are moreover bound by their articles of union to remain democratic in constitution. The best work on the federative governments of antiquity is that of St. Croix, *Des Anciens Gouvernements Federatifs.*

FEE-FARM RENT, in Law, is defined a rent charge in fee, issuing out of an estate in fee of at least one quarter of the value of the land at the time of its reservation. Some authorities consider the amount as immaterial. No grant in fee farm can be made since the statute of Quia Emptores.

FEE'LERS. Organs fixed to the mouth of insects, generally less than the antennæ, and often jointed. *See* PALPS.

FEES. In Law, perquisites allowed to ministers of justice, fixed either by act of parliament or ancient usage. The word fee is derived either from an Ang. Sax. word signifying *money*, or the French foi, *faith.*

FEE SIMPLE, in Law, is an estate of freehold of inheritance in lands, tenements, or hereditaments. Tenant in fee simple absolute, or, as it is more briefly expressed, in *fee*, is one who has the fullest power of disposing of his tenement which the law allows; and not being disposed of by him either in his lifetime or by devise, it descends to his heirs general.

An estate to a man and his heirs qualified by a condition or limitation capable of abridging it, as an estate to A. and his heirs on condition of paying a sum of money on a stipulated day, and if he fail to do so then to another, is termed a fee conditional; or, with less propriety of language, a fee-simple conditional.

FEE TAIL, in Law, arose out of the statute *De Donis*, 13 Edw. I., which restrained the alienation of lands and tenements by one to whom they had been given, with a limitation to a particular class of heirs. A gift, for instance, to a man and the heirs of his body, constituted before the statute a fee-simple conditional, which could be alienated as soon as a child was born to the donee: after the statute it became inalienable, until more latitude was given by the invention of certain refined fictions of law.

A deed creating an estate tail is properly called a gift, and the giver and receiver the *donor* and *donee*. Estates tail are *general*, where only one person's body is specified from which the issue must be derived; *special*, where both the progenitors are marked out, as in a gift to A. and the heirs of his body to be begotten upon B. It may also be descendible to all the issue, or to male or female issue; in which case estates are said to be in tail male or in tail female. Half blood is no impediment in the descent of an estate tail general. Where lands and tenements are given to a man and his heirs in special tail (by a wife named in the grant), and the wife dies without issue, the husband is tenant in tail after possibility of issue extinct; and his estate is in most respects equivalent to one for life only.

Estates tail being contrary to the general policy of the law, legal ingenuity was taxed, in early times, to invent modes whereby they might be defeated; *i.e.* whereby the donee might destroy the special limitations of the gift, and acquire an estate in fee simple without incurring forfeiture. This was done by the fiction of *common recoveries* (of which the validity was established in the courts in the reign of Ed. 4.), and by that of fines, recognized by statute (4 H. 7. c. 24., 32 H. 8. c. 36.) A simpler process has been substituted for these ancient contrivances by the recent Real Property Act (3 & 4 W. 4. c. 74.)

FELIS. (Lat. *a cat.*) The name given by Linnæus to the genus of Ferine or carnivorous quadrupeds of which the common cat is an example. The essential characters of this genus repose on the strong, sharp, retractile talons with which all the four feet are armed, and the corresponding destructive nature of the dentary organs. These consist of six small incisors in each jaw, the exterior ones larger than the rest; two long and strong laniaries, bounding the series of incisors in the lower jaw; and two in the upper jaw of still greater length and strength, conical, sharp-pointed, slightly incurved, and separated from the incisors by an interval corresponding in size with the summits of the inferior laniaries, which always pass, when the mouth is closed, in front of those of the upper jaw.

The molar teeth are four in number on each side of the upper jaw, and generally three on each side of the lower; the two anterior in each series are smaller than the third, and furnished each with a single conical pointed middle process. The third molar is the largest in both jaws, and presents a very characteristic form in the lower one being compressed, and terminating in two sharp-pointed trenchant triangular lobes, which play upon the inner surface of three corresponding lobes of the tooth above: the appulse of the lower carnassial or sectorial tooth is checked, and the upper gum defended, by an internal tubercle in the upper sectorial. The fourth molar in the upper jaw is placed within the posterior margin of the third, and presents a simple transverse slightly convex plate, affording additional surface for the inferior sectorial to work against. The claws and teeth above described are better adapted for the seizure and destruction of living animals than are those of any other mammalia; and the power of wielding these weapons is enjoyed in a corresponding degree of perfection. There are no quadrupeds in which the muscles of the jaws and limbs are more fully developed. The teeth, as we have seen, are few, though formidable: those of the lower jaw occupy only its anterior half; the rest of the jaw consisting chiefly of a broad and high coronoid, and a strong angular process for the implantation of the immense muscles destined for its movements. The skeleton of the feline animals presents a light but well-built mechanism: the bones, though slender, are extremely compact; the trunk, having to contain the simple digestive apparatus requisite for the assimilation of highly organized animal food, is comparatively slender, and flattened at the sides. The muscular forces are thus enabled to carry the light body along by extensive bounds, and it is thus that the largest felines generally make their attack. When the impetus of the spring is added to the stroke of the paw, the lion or tiger has power to fell an ox, or smash the skull of a man at a single blow; and as the strength of the neck corresponds with that of the jaws and limbs, they are enabled to bear away with ease animals bigger and heavier than themselves. It fortunately happens that the feline animals have not the instinct of sociality, otherwise what terrestrial species could withstand a troop of lions or tigers hunting in concert like a pack of wolves? "Conscious of their own undisputed superiority," says the author of a favourite zoological work, "which secures them against the attacks of other animals, each with his female partner occupies a solitary den, which is usually concealed in the depths of the forest. Hence, when pressed by hunger, they issue forth in search of their prey, which they rarely attack with open force; but stealing on with noiseless tread, or stationing themselves in ambush in such situations as appear suitable to their purpose, watch with indefatigable patience the approach of their victim. Their motions are peculiarly characteristic of their habits and mode of life. Incapable of long-continued speed, their usual gait is slow, cautious, and stealthy, with their posterior limbs bent beneath them, and their ears distended to catch the most trifling noise. Guided by these organs, the internal structure of which is highly developed, they trace the sound of footsteps to an almost incredible distance, and direct themselves towards their prey with unerring certainty. In this quest the sense of smell, which they possess in a very low degree, affords them but little assistance; their sight, however, is good, and serves them equally well both by day and night, their extremely dilatable pupils adapting themselves with admirable precision to various intensities of light. To this object the frequently elongated form of their pupils, the light green or yellow colour of a large portion of the choroid coat of their eyes, and the extent of their nictitating membrane must also essentially contribute.

"No sooner is the object of their pursuit within reach of their attack than, suddenly bursting forth from their lurking place, or changing their slow and stealthy pace for a furious and overwhelming bound, they dart with the velocity of lightning upon their terrified victim. The great strength and extreme flexibility of their fore-paws enable them at once to dash him to the earth, and to seize him with an irresistible grasp. They then proceed

to rend him in pieces by the united efforts of their teeth and claws, and gorge themselves upon his lacerated flesh."

The feline animals or cats constitute a well-defined and circumscribed genus. The leopards, panthers, jaguars, and tigers are the most typical or truly feline species; in these the beauty of colouring, sleekness of skin, elegance of form, craft, suspicion, bloodthirstiness, agility under excitement, and sloth during repletion, are most strongly manifested. The lion combines more robustness of body with the feline attributes; and his pre-eminent stature receives an air of nobility and grandeur from the mane that decorates his head and neck. He has the credit, too, of a greater share of boldness and generosity than the other cats. His vocal organs also exhibit a modification of structure not present in the other felines, by which he has the power to utter his tremendous roar; —a roar which, when sent forth under the excitement of hunger, scares from their hiding places the timid ruminants which may be lurking within the compass of its fearful reverberations. Among the felines, one group is characterized by the shortness of the tail, and the tuft of hairs on the tip of the ears; this includes the lynxes.

The cheetah, or hunting leopard, deviates most in the half-retractile condition of the talons and the upright carriage of his body from the true feline characters; and with these physical modifications is combined so much of the canine disposition as enables this species to be used in packs for the purposes of the chase.

The middle-sized cats, which lurk in the branches of trees, as the leopards, ocelots, &c., have a fulvous ground colour, broken by irregular dark spots; a marking which admirably adapts them for concealment amidst foliage. A similar relation of adaptation to the peculiar theatre of their destructive habits may be traced in other species. The tiger, for example, which prowls on the ground, and creeps stealthily towards his victim between the stems of the trees and plants of the jungle, has his bright ground colour interrupted with black vertical stripes. The lion, which traverses the parched deserts of Africa, and lies in wait to intercept the antelopes which bound in troops from one oasis to another, would be rendered too conspicuous if his tawny hide were ornamented by the stripes or spots that characterize the feline livery; these, therefore, which are obvious enough in the earlier periods of his existence, become obliterated as he attains to maturity. A smaller feline species, the puma, or American lion, which plays the predatory character in a corresponding theatre of the New World, presents a similar uniformity of colour.

The feline animals bring forth from two to six young ones at a birth. The domestic cat is the most fertile; a circumstance which arises from the abundance of food, shelter, and protection consequent on her alliance with man. But, as has been frequently remarked, this, of all domesticated animals, is the least servile or restrained; and though instances of personal attachment are not wanting, the affection of the cat is rather to the house than to its owner. There are many singularities in the nature of the cat, which perhaps our comparatively limited acquaintance with the other felines leads us to regard as peculiar to this species. She is remarkably nervous, and readily startled; gives out the electric spark when her fur is rubbed contrary to its direction, as is very conspicuous when this is done in the dark. Under the excitement of fear, the same effect is produced on the long hairs of the tail as if a stream of electricity were transmitted through them, and they all stand out from the surface to which they are attached, giving the tail an appearance of treble its usual thickness; at the same time the back is raised, and the body drawn into its smallest compass. Cats are attracted by peculiar odours, and exhibit a violent fondness for catmint and valerian, rubbing their noses and rolling themselves in the latter with signs of great and uncontrollable excitement. Cats are very cleanly, are fond of warmth, and seek a soft place for their repose. They express their satisfaction by a peculiar soft vibrating noise. called "purring."

FE'LLING TIMBER. In Arboriculture, when a full-grown tree is cut down it is said to be felled; but this term is never applied to young trees or bushes, undergrowth, or hedges, which are said to be rooted out or cut over. Much has been written respecting the proper season for felling trees; some arguing in favour of midwinter, and others in favour of midsummer. The question principally turns upon the quantity and the value of the soft or outer wood in the trunk of the tree to be felled known by foresters and carpenters as the sap. As this sap or outer wood is the only portion of the trunk in which the sap or juices of the tree circulate, it is evident that if no value be set upon it the tree may be cut down at any season; because the truly valuable part of the trunk, the mature timber, is impermeable to the sap in its ascent through the soft wood, and is therefore in the same state at every season of the year. On the other hand, where much value is attached to the soft or outer wood, where this outer wood is wished to be made as valuable as possible, or where, as in the case of comparatively young trees, the greater part of the trunk consists of sap wood, felling ought to take place when there is least sap in the course of circulation. This season is without doubt midwinter, which, all other circumstances being equal, is unquestionably the best season for felling timber; the next best being midsummmer, when the sap is chiefly confined to the young shoots, the circumference of the soft wood, and the bark: as the worst is the spring, just before the development of the buds, when the tree is fullest of sap, and receiving constantly fresh supplies from the root; and in autumn, immediately before the fall of the leaf, when there is a superabundance of sap, from its being as it were thrown out of employment by the falling of the leaf. In general, all the soft woods, such as the elm, lime, poplar, willow, &c., should be felled during winter; hard woods, like the oak, beech, ash, &c., when the trunks are of large size, and valued chiefly for their heart wood, may be felled at any time.

FE'LLOW. In the colleges of the English Universities, and some other collegiate institutions, the superior members of the foundations are so termed in general. In some, however, all members of the foundation are fellows from their admission. The usages of different foundations in the two universities vary so materially, that no general account will apply equally to all. The fellows are, in general, graduates; elected either on free competition, or according to limitations fixed in the statutes of foundation. Most fellows are obliged to abandon their fellowships if they do not take orders at a certain period: there are, however, lay fellowships in both universities. Fellowships are also vacated in the universities (without exception) by marriage; and by the acceptance of preferment in the church from the college, or in some instances of other preferment of a certain value. From among the resident fellows are selected for the most part the governing officers and tutors of the colleges. The principal or head of the college is generally elected either by the whole or a select body of the fellows. There is a distinction in some colleges between senior and junior fellowships, in point of emolument, which does not exist in others. At Cambridge there is also a distinction between foundation fellowships and bye or appropriation fellowships; the former only, in most colleges, entitling the possessor to college offices. The value of fellowships is extremely various; nor do they always maintain the same amount, being generally dependent on corn-rents. The advantages obtained by the fellow are partly in income, partly, if resident, in free lodging and allowances towards board. There are fellowships of the value of 500*l.* or 600*l.* per annum, and others of 100*l.* or less; but a large proportion may be said to average from 150*l.* to 300*l.* a year. *Fellow* is also the general title of members of learned academies and societies in England.

FE'LLOWSHIP, or PARTNERSHIP. A rule in Arithmetic, of considerable use in balancing accounts among partners in trade. Considered as an arithmetical process, it is simply a method of dividing a number into parts which shall have given proportions to each other. Fellowship is either simple or compound. To simple fellowship belongs a question of this sort:—"A contribution of 20,000*l.* is levied on three towns, and each is required to pay in proportion to the number of its inhabitants. Now the 1st contains 2000 inhabitants, the 2d 3000, and the 3d 5000; what sum must each contribute?" This question is obviously the same as if it had been required to divide the number 20,000 into three parts, having the ratios of 2, 3, and 5, which is done by dividing 20,000 by the sum of 2, 3, and 5, that is by 10, and multiplying the quotient by each of those numbers separately; the several results are the sums required. Here $20{,}000 \div 10 = 2000$; and $2000 \times 2 = 4000$, for the share of the first; $2000 \times 3 = 6000$, for the share of the second; and $2000 \times 5 = 10{,}000$, for the share of the third. These results are in the given proportions, and their sum amounts to 20,000.

Compound fellowship is when the parts into which the given number is to be distributed are proportional to more than one set of numbers. This is usually called *fellowship with time*, because in distributing the profits of a mercantile transaction carried on by several partners the share of each must be proportional, both to the amount of the capital he contributed and to the time it was employed. It must therefore be proportional to the product of these two. Hence the rule for compound fellowship:—Multiply each stock by the time of its continuance, the products are the numbers to which the several parts of the sum to be distributed must be proportional; and with these numbers proceed, as in the case of single fellowship. Both cases, it may be remarked, belong to what is more correctly termed *Distributive Proportion*.

FE'LO DE SE. In Law, one who is found by the coroner's jury to have laid violent hands on himself, or occasioned his own death feloniously. This verdict occasions forfeiture of chattels, real and personal; but not of lands of inheritance. One found felo de se was formerly buried in the king's highway, with a stake driven

through the heart; but since 1823 (4 G. 4. c. 52.), privately buried in a burial ground, between the hours of nine and twelve at night.

FE'LONY. (A word of uncertain derivation. Sir H. Spelman derives it from the word fee or fief, and the Teutonic lohn, *reward* or *price;* that which costs or forfeits land. More probably from the same root with the verb *to fail.*) In Law, in the general sense, comprises every species of crime which occasioned at common law the forfeiture of lands and goods. Treasons, therefore, are, strictly speaking, felonies, though in common language distinguished from them. The term felony appears, in feudal law, to have been synonymous with forfeiture to the feudal lord. The general punishment attached to felony at common law was death; and if any statute, even now, makes a new offence felony without specifying the punishment, the law implies it to be capital. But some species of felony were not thus punishable at common law; and the gradual operation of altered opinion upon our code has removed this punishment from all but a few. The principal species of felony are, — 1. Offences against the person, such as murder, manslaughter, rape, &c.; assault with felonious intent, that is, with intent to injure the sufferer in a greater or less degree. The highest of these offences against the person are still punishable by death. The acts respecting these offences were consolidated by 7 & 8 Geo. 4. c. 31. Some of them, as common assaults, &c., are only misdemeanors. 2. Of offences against property, the great body is comprehended under the ancient appellation of *larceny.* 3. Embezzlement. 4. Burglary. 5. Malicious mischief to property, arson, riotous demolition of churches, chapels, houses, &c., are capital offences within this class. 6. Forgery. 7. Numerous offences of a public nature (many such, however, amount only to misdemeanor) — 1. Either against the king and government, as treason, sedition, embezzlement of the king's stores, &c.; 2. Against public justice; 3. Against the public peace; 4. Against public trade; 5. Against public police and economy. Under this head also are to be ranked some offences relative to game, while others come under the description of larceny.

FE'LSPAR. (Germ. feldspath.) An important mineral composed of silica, alumina, and potash, with traces of lime, and often of oxide of iron. Common felspar is of various shades of white and red; it forms an ingredient in granite, and is the base of some other rocks. It is often crystallized, and cleaves into rhomboidal fragments.

FE'LTING. (Germ. filzen.) The process by which different kinds of fur or wool are blended into a compact texture for the manufacture of hats. The anatomical peculiarities of the different hairs or furs are much concerned in the perfection of the felt; they must be such as to enable them to interlace and intertwine with each other. Hare and rabbit fur, wool, and beaver, are the chief materials used; they are mixed in proper proportions, and are tossed about by the strokes of a vibrating string or bow till they become duly matted together.

FELU'CCA. (Span. faluca; Fr. felouquer; Ital. feluca.) A small vessel, carrying two masts, and propelled by oars and sails, used chiefly in the Mediterranean and on the adjacent coasts for coasting voyages. Small war boats used in the same quarter are also so called.

FEMME COVERT. In Law, a term borrowed from the French to signify a married woman.

FEMUR. (Lat. *a thigh.*) In Vertebrate Anatomy, the first bone of the leg or pelvic extremity; in Entomology, the third joint of the leg, and is long, and usually compressed.

FEMUR. In Architecture, the interstitial space between the channels in the triglyph of the Doric order. These femora are sometimes called the legs of the triglyph.

FENCE. Any continuous line of obstacle interposed by art between one portion of the surface of land and another for the purpose of separation or exclusion. The kind of obstacle or material differs according to the animals which are to be separated, excluded, or confined, and the nature of the soil and situation. All fences are either live or dead, or a compound of these. Live fences are hedges; that is, rows of shrubs placed close together, and pruned on the sides, so as to form a sort of living wall. Dead fences are either stone walls, mounds of earth, or structures of wood or of other materials raised above the ground's surface, or upon ditches excavated in it. The latter are sometimes filled with water. Mixed fences are those in which some kind of dead fence is used with some kind of live fence; for example, a ditch with a bank of earth on one side, or a ditch with a wall or a hedge on one side; the latter the commonest of all fences. The introduction of fences into agriculture was about as great an improvement in the progress of that art, as that of the principle of the division of labour into the art of manufacture.

FE'ND OFF. The sea term for pushing off a boat or any heavy body to break the shock or avoid contact.

FENE'STRATE (Lat. fenestra, *a window*), in Entomology, signifies the naked hyaline transparent spots on the wings of butterflies.

FE'N LANDS. Lands, the subsoil of which is constantly in a state of saturation with water, and the surface is liable to be overflown by rivers or streams during spring or autumn. The soil of these lands is generally black, light, and rich, to the depth of two or three feet; and as the surface water readily filtrates through this soil to the subsoil, fen lands generally produce bulky crops of grass and corn. As they have very seldom any natural outlet for drainage, this is generally performed by machinery; and when this is the case few lands are more productive. Till lately windmills were employed for draining the English fens; but steam is now frequently had recourse to as the moving power, and the advantages to the cultivator are immense; because he can lay his lands dry at the season when it is most convenient that they should be so, whereas the operation of the windmill is always a matter of chance. For an account of the Fens in England, see *British Statistics;* and *M'Culloch's Geographical Dict.*, art. "Bedford Level."

FE'OFFMENT. In Law, a species of conveyance. It was in early times the public and solemn mode of alienating lands and tenements in possession, and was performed by a deed, accompanied by livery of seisin; which last was the delivery of the land itself, effected by certain symbolical acts and customary words. As secret conveyances to uses gradually prevailed, feoffments fell comparatively into disuse. The grantor is termed the feoffor, and the person receiving the feoffee.

FERÆ. (Lat. ferus, *wild.*) The name given by Linnæus to the order of Mammalia comprehending those which subsist more or less exclusively on the flesh of other animals. They are characterized by having three kinds of teeth, incisors, canines, and molars; unguiculate extremities, without an opposable thumb on the fore foot, but with the power of rotation in the forearm. This order corresponds with the *Insectivora*, and the Plantigrade, Digitigrade, and Pinnigrade *Carnivora* of Cuvier's *Carnassiers.*

FE'RGUSONITE. In Mineralogy, a crystallized compound of columbic acid and yttria with a small quantity of zirconia, and of oxides of tin, cerium, iron, and uranium. It has hitherto only been found in Greenland.

FE'RIÆ. In Roman Antiquities, solemn religious festivals. The most celebrated were the Feriæ Latinæ (Latin holidays), celebrated on the Alban mount by all the states of Latium in common. The deputies of the various cities, with those from Rome, met on the Alban mount, where, under the presidency of the latter, they sacrificed a bull to Jupiter Latialis, and under sanction of this ceremony took oaths to preserve their mutual friendship and alliance. This festival was originally instituted by the second Tarquin, in whose time and long subsequently it lasted for one day only; but in process of time it extended to four. It was observed by the consuls regularly before they set out for their provinces.

FERINES. (Lat. ferus, *wild.*) The English equivalent of the *Carnassiers* of the system of Cuvier; but generally employed to designate the group corresponding with the *Feræ* of Linnæus, and excluding the bats (*Cheiroptera*), which form the first family of Cuvier's *Carnassiers.*

FERMENT. (Lat. ferveo, *I boil.*) The substance which is essential to the process of fermentation. It is either naturally present in the fermentable juice, as in the grape; or it is added, as in the manufacture of beer, where *yeast* constitutes the ferment. Ferments are of an albuminous or glutinous character; the presence of nitrogen seems essential in their composition, hence they are classed by chemists among azotised compounds. Their modus operandi is still unexplained.

FE'RMENTA'TION. (Lat.) When certain vegetable substances are dissolved in water, and subjected to a due temperature (between 65° and 85°), they undergo a series of changes which terminate in the production of alcohol or spirit; these changes constitute the phenomena of *vinous fermentation.* Sugar and some ferment are essential to the process; and during the formation of the alcohol the sugar disappears, and carbonic acid is more or less abundantly evolved. The simplest case of fermentation is that of *must*, or of the expressed juice of the grape, which when exposed, either in close or open vessels, to a temperature of about 70°, soon begins to give off carbonic acid, and to become turbid and frothy; after a time a scum collects upon the surface, and a sediment is deposited; the liquor which had grown warm gradually cools and clears, loses its sweet taste, and is converted into *wine.* The chief component parts of must are water, sugar, mucilage, gluten, and tartar. During the fermentation carbonic acid escapes, the sugar disappears, and with it the greater part of the mucilage; the gluten chiefly forms the scum and a portion of the sediment; and the tartar, originally in solution, is thrown down in the form of a coloured deposit. It appears, therefore, that the new products, which are *alcohol* and *carbonic acid*, are principally formed at the expense of the sugar; and Gay Lussac's

experiments have shown that 45 pounds of sugar are resolved, in the process of fermentation, into 23 of alcohol and 22 of carbonic acid. Sugar and water alone will not ferment; the ingredient requisite to the commencement of the change is the gluten, which absorbs in the first instance a little oxygen from the air, becomes insoluble, and induces the subsequent changes. The reason why grapes never ferment till the juice is expressed, seems to depend upon the exclusion of air by the husk or membranes; and if grapes be bruised in a perfectly close vessel, carefully excluding oxygen, the juice undergoes no change; so that the mere breaking down of the texture of the fruit is insufficient. But a very short exposure of the pulp to air is sufficient to induce that change in the juice which leads on to fermentation, and which is afterwards independent of the further contact of air, the evolution of carbonic acid being exclusively referable to the decomposition of sugar. In *beer* the alcohol is derived from the sugar, original and produced, of the malt. When wine is exposed to air and a due temperature, a second fermentation ensues, which is called *acetous fermentation*, and which terminates in the production of *vinegar*. During this process oxygen is absorbed, and more or less carbonic acid in most cases evolved; but the apparent cause of the formation of vinegar is the abstraction of hydrogen from the alcohol, so as to leave the remaining elements in such proportions as to constitute *acetic acid*. Thus alcohol is theoretically constituted of charcoal, water, and hydrogen; and acetic acid of charcoal and water only: the oxygen of the air, therefore, converts the hydrogen of the alcohol into water, and so effects the change into vinegar.

FE'RMO. *See* CANTO FERMO.

FERN ROOT. The root of the *Aspidium filix mas*, or male fern. About two drachms of the dried root, in powder, followed up by a brisk purge, is occasionally given as a vermifuge. It was Madame Nouffer's celebrated specific.

FERNS. Cryptogamic plants of the highest grade of development, and more especially remarkable for the perfect manner in which their leaves are formed. *See* FILICES.

FE'RRO-CYA'NIC ACID. A compound of 3 atoms of cyanogen, 2 of hydrogen, and 1 of iron. It is the *ferro-chyazic acid* of Mr. Porrett, the term *chyazic* being composed of the initials of carbon, hydrogen, and azote, which are the ultimate elements of hydro-cyanogen.

FERRU'GO. In Botany, a disease of plants, commonly called rust. It is caused by the presence of myriads of minute fungi, chiefly of the genus *Uredo*, which are to plants what intestinal worms are to animals.

FE'RRY. (Germ. and Sax. fahren, *to pass over*.) In Law, a right arising from royal grant or prescription to have a boat to carry men and horses across a river, and to levy reasonable toll. The land on both sides ought to belong to the owner.

FE'RULA. A genus of Umbelliferous plants with thin flat fruit resembling that of the parsnip, and yellow flowers. The species are chiefly natives of Persia, where they yield the drug asafœtida. According to Kæmpfer this fetid gum-resin is an exudation from the root of *F. asafœtida*; but there is no doubt that it is also produced by several other species.

FE'SCENNINE VERSES (Verses Fescennini), so called from Fescennia, an Etrurian town, where they first had their origin, were rude extemporaneous pieces of poetry recited by the youth of Latium and Etruria at rustic festivals, especially at harvest home, with gestures adapted to the sense. They consisted principally of raillery and playful rustic abuse; a species of humour very much in vogue with the Grecian and Egyptian country people also. The Fescennine verses are chiefly remarkable from having given rise to satire, the only class of poetry of native Italian growth.

FE'SCUE GRASS. A valuable grass for meadows and pastures. (*Festuca pratensis*, Lin.) In deep rich soils somewhat moist it is considered as the most bulky and nutritive of all grasses; but in poorer soils it is equalled, if not surpassed, by the rye grass (*Lolium perenne*), and the meadow foxtail grass (*Aleopecurus pratensis*). The meadow fescue grows to the height of between two and three feet; but the sheep fescue (*F. ovœna*), and several other species, seldom grow above six inches or a foot in height, and are chiefly sown on sheep pastures, and used to lay down lawns and grassy surfaces to be mown in pleasure grounds. All the fescues are perennials; and they are all natives of Britain.

FESS. (Lat. fascia, *a wide belt.*) In Heraldry, one of the ordinaries. It is bounded by two horizontal lines across the escutcheon, equally distant from the *fess point* or centre of the escutcheon. A fess not reaching to the sides of the escutcheon is said to be *couped* (cut) or *humetty*. The diminutives of the fess are the *bar*, the *closet*, and the *barulet*. A fess with a barulet on each side of it is said to be *cotised*. A fess removed to the top of the escutcheon is termed a *chief*, and held to be an honourable augmentation.

FESTOO'N. (Fr. feston.) In Architecture, a carved representation of a wreath or garland of flowers, or leaves and fruit, or all of them, interwoven together; thick in the centre and small at each extremity, where it is fastened, and frequently turned over.

FE'TIALS. *See* FECIALS.

FE'TICH, *Fetichism*. The word Fetich is said to be derived from the Portuguese; and appears to have been brought into common usage from the writings of some travellers on the western coast of Africa. It is now comprehensively employed to signify any object of worship not representing a living (or rather perhaps a human) figure; thus excluding idols, properly so called. Fetichism is the worship of material substances. This perverted form of religion prevails very extensively among barbarous nations, and especially those of the Negro race. Among the latter, tribes, families, and individuals have their respective Fetiches; which are often objects casually selected, or chosen under the influence of some occasional superstition, as stones, weapons, vessels, plants, &c. &c.

FE'TLOCK. (Quasi *footlock*, whence the derivation.) In the *Manege*, a tuft of hair growing behind the postern joint of horses; hence the joint where it grows is called the fetlock joint.

FE'TTERED, in Zoology, is applied to the feet of animals when they are stretched backwards and appear unfit for the purpose of walking; or when they are concealed within the integuments of the abdomen.

FE'TTSTEIN. (Germ. *fat stone.*) *See* ELAOLITE.

FEU (Lat. feodum, *fief*), in Scottish Law, is used in contradistinction to *ward-holding* or military tenure, to signify that holding where the vassal makes a return in grain or money in lieu of military service. The *feu contract* is that which regulates the giving out of land, as between superior and vassal; the rent paid being termed the *feu duties*.

FEU'DAL SYSTEM. (From the modern Latin word *feodum* or *feud;* in English *fief* or *fee*.) A body of institutions of a peculiar character, introduced into Europe by the German and Gothic tribes which conquered the provinces of Rome, which prevailed for a long period, and has left important traces of its existence in most European countries. The words fief and feud are both, it is conjectured with much probability, corruptions of the Græco-Latin term *emphyteusis* (pronounced emphytefsis), signifying a contract whereby an individual acquired the enjoyment of a piece of land without the absolute property in it. Hence by contraction came *fef* or *fief*, and by the addition of a neuter termination *fevodum, feudum, feodum*. Another derivation, recently suggested, is from the Irish "fuidhur," "fuidh," signifying, in the Brehon Laws, a stranger who enjoys land within the domains of a clan, and the tenure by which he enjoyed it. It is singular that the word "vassal" is also probably of Celtic derivation. (*See* VASSAL.) The English word "feud" (quarrel or strife) is of an entirely distinct origin, being the same with the German *fehde*. The German equivalent for *fief* is another original word, *lehn*.

It is clear that feudal usages were absolutely unknown to the ancient Romans; but as among that people, and especially in the later times of the empire, there existed certain customs which were analogous in appearance, although not in origin, — such as the establishment of military colonies on the frontier, where the tenant of land was a soldier, and liable to be called into active duty; and the cultivation of great part of the empire by *coloni*, a distinct class of men, raised above the condition of the slave, and yet bound to render services to the proprietor, and in some instances annexed to the soil,—the barbarians in many instances adapted the conventional language and the laws of Rome to their own native customs; thus producing a confusion of idiom and practice, of which a better instance cannot be found than the fact already mentioned, that the word "feud" itself is derived from a legal term of the Greek empire (emphyteusis).

The immediate result of the conquest of Gaul, Italy, and Spain by the various barbarian tribes, was the division of the lands (except such portions as were left in the possession of the Roman cultivators and only rendered liable to tribute) between all the armed men of the nation. The shares were undoubtedly unequal even in the earliest of these divisions; but however differing in point of wealth, all the free proprietors were equal in rights: all were held liable to serve with the national force when called into the field; all had a voice, at least nominally, in the making of laws and in the choice of a sovereign. These free citizens are called by various names in the legislation of the different tribes; the Lombard title of *Arimannus* (ehren-mann, *man of honour*, or heer-man, *warrior*) seems to have been the most permanent. Such, however, was the general constitution of the kingdoms of the Lombards in Italy; the Franks in Gaul; the Visigoths, Ostrogoths, and Burgundians; and of the various states which grew up within the limits of Germany itself, after the confusion occasioned by the great migrations had passed away.

The decay of these aristocratic republics was brought about by nearly the same causes which operate in under-

mining all systems founded on equality of rights and classes. The constant wars and vicissitudes to which these governments were subject naturally raised up among the citizens some more powerful than the rest, and converted a great body of the freemen into dependents upon these. The dukes and counts, and other great men, became the actual controllers of the community: the free citizens, wherever unable to associate for mutual protection, were subject to innumerable vexations. From the earliest times, and before the fall of the Roman empire, it had been customary among the Germans for the princes and chief men to be attended by a select body of faithful companions, whose dependence on them, and services due to them, were recognized and fixed by general usage. This custom, under the new circumstances of the Germanic and Gothic kingdoms, acquired peculiar force. It became an object of ambition to the chieftains to have as many dependents as possible. With this view, every species of vexation was exercised by them towards the unprotected Arimannus, to induce him to abdicate his own independence, and enrol himself under their command. During the wars and confusions of the eighth and ninth centuries, the foundations of the feudal system were laid by this personal dependence assuming gradually the character of a territorial dependence also. The Arimannus was induced to surrender up his free or allodial lands to the king or count, and became his "liegeman" (fidelis), "antrustion" (our English word *trust* comes from the same origin), "vassal," or "man" (homo, whence *homagium*, homage), receiving back his lands to hold of the superior. This process can only now be traced by insulated documents and historical facts; but, arising out of the same circumstances in most countries of Western Europe, it took in all of them nearly the same course. It is ably developed by Hallam (in his first chapter on the *Feudal System*), and Meyer (*Institutions Judiciaires*, livre i.).

The success and energy of Charlemagne arrested for a time the decomposition of the old form of society; his empire extended over nearly all those portions of Europe which afterwards became feudal; and his various laws (in the end of the eighth and beginning of the ninth century) present us with a remarkable picture of what may be called the state of transition from the allodial to the feudal system. We find in them that the free proprietors, or Arimanni, still formed a very numerous body; and that the exigencies of military service fell most heavily upon them. They were obliged to serve at their own cost; while the counts, &c. brought their vassals to the field at their own expense. These laws are full of the vexations endured by the former class from the powerful military chieftains. On the other hand, the practice of attaching individuals to the person of the sovereign or superior by the grant of lands (*benefices*), and the obligations imposed on the inferior by the grant, are clearly developed. The distinction between *allodial* and *feudal* lands (though the latter term was not yet used) is as marked as at any subsequent period. But benefices were not yet hereditary: it is doubted by the most learned writers, whether or no they were, generally or frequently, precarious and revocable.

The decay of Charlemagne's empire, and the disasters of the two centuries which followed his reign, completed the formation of the feudal system. The great step by which that change was completed was when the benefices or fiefs became, like the former allodial properties, hereditary. There can be little doubt that this change was merely the result of those disastrous circumstances of civil and barbarian wars which during that period relaxed the slight bonds of the Carlovingian monarchy, and rendered every man as far as possible dependent on an immediate superior, and independent of a central authority. The earliest express creation of an hereditary fief is considered to be the donation of the duchy of Aquitaine to Eudes and his heirs by Charles-le-Chauve. The great vassals established their families permanently in the lands which they held of the fisc or royal domain: their liegemen, in turn, were gratified by acquiring the same right in their own subordinate fiefs. There can be no doubt that the nobility of modern Europe owes its origin, in general, to nearly the same period and the same causes: those families which succeeded in acquiring extensive fiefs, and preserving them for several generations, became noble by prescription. In the meantime, the Arimanni, or allodial proprietors, found their condition became worse from generation to generation; they were loaded with services and dues until, in the tenth century (as is shown by Meyer), the term "arimannia" became synonymous with exaction. But although the feudal system became so generally prevalent, that the maxim "Nulle terre sans seigneur" (importing that lands were presumed feudal until the contrary was shown) became generally received, yet in France and Germany they never became wholly extinct. In some districts of the former country the maxim was reversed, and lands were presumed allodial. (See *Hallam*.)

Character and Features of the Feudal System.—This institution is generally supposed to have been fully consolidated by the commencement of the eleventh century: the law of Conrad, the Salic, in Lombardy (1039), contains all its main features: the *Assises de Jerusalem*, and other compilations, show that in a century more it had been invested with all the refinements of a legal system.

By the principles of this system, the king was, in the last resort, proprietor of all the feudal lands of his kingdom. Those who were infeoffed of lands directly from the crown, and owed homage and service to the king, were termed tenants in chief (in capite), &c. These, again, infeoffed other inferior tenants, who held immediately of them; and this practice (called sub-infeudation) might be carried on through several gradations. Thus the same individual was a *vassal* or dependent of the crown, and *lord* or *suzerain* with reference to his own vassal who held of him, also termed *mesne* or mediate lord, a term which comprehended both these relations. But although all perfect fiefs resembled each other in their theoretical character, and particularly in their great attribute of military service; yet, in point of fact, tenants holding immediately of the crown stood in very different degrees of subordination. Thus, in France, the great vassals (the Dukes of Normandy, Britany, &c.) were immediate tenants of the crown, but in effect almost independent of it; while they exercised much stricter sovereignty over their own immediate tenants. But other lands, being the demesne of the crown itself, were held of it by lesser tenants in chief, who stood to the king in the same close relation as the vassals of the great feudatories did to them. Thus the government of France, at the period when the feudal system was in greatest vigour, was that of a collection of independent sovereigns, of whom one, the king, had a certain supremacy over the rest; but each, within his own domains, exercised an equal authority: and such was, in theory at least, the constitution of every feudal kingdom. The ceremonies used in conferring a fief were chiefly three:—1. *Homage*, by which the vassal owned the lord's supremacy; but *homage per paragium*, or simple homage, was unaccompanied by any feudal obligation; homagium ligeum, or liege homage, implied such obligations: the former only was rendered to the king by the great feudatories above mentioned. (See *Hallam's Middle Ages*, c. 2. part 1.) 2. The oath of *fealty*. 3. *Investiture*, or the conveyance of feudal lands, actual or symbolical. The chief *obligation* of a feudal tenant was military service; but the laws which regulated this essential part of the contract were so various, that it is not possible to give any comprehensive description of them. In some places every tenant was obliged to serve personally for his fief, whether large or small; in others (as England), the land was divided into a certain number of equal parcels, from each of which a soldier's service was due: the term of service was also variously regulated by custom. The conflicting rights of superior and inferior lords to the vassal's military service were also never satisfactorily adjusted. When feudality was in its most flourishing state, he commonly followed the banner of his immediate superior, even against the crown; but with the progress of the royal power, his obligations were gradually transferred to the king as lord paramount: military service was in most cases rendered commutable, in process of time, for an amercement in money. (*See* ESCUAGE.) There were other inferior obligations which attached to the military tenures, commonly called feudal incidents. These were chiefly, 1. *Reliefs;* i.e. sums of money paid to the lord by tenants of full age on taking fiefs by descent. 2. *Fines* upon alienation, which were sums paid on alienating a fief; a privilege which was only gradually acquired by feudal tenants, being contrary to the principles of the institution. 3. *Escheats;* i.e. the reversion of the fief to the lord, on failure of the tenant's heirs or forfeiture. 4. *Aids;* sums paid by tenant to the lord on certain specified occasions. And to these may be added the feudal rights of *wardship*, by which the lord, in some countries, had the custody of his tenant's person, and the enjoyment of his lands until he was of full age; and *marriage*, by which the lord had the right of disposing of such ward's land in marriage, or, if the marriage were rejected, to a sum of money equivalent to the marriage, *i.e.* as much as it was presumed the party seeking the marriage would have given the lord for the alliance. Forfeiture of the fief to the feudal lord was incurred by the tenant's violating any of the original conditions of fealty, homage, and military service. But the vassal was protected from the unjust aggression of the lord by that which seems to have been an inherent and necessary condition of the feudal system; the judgment, namely, of his peers, without which such forfeiture could not be incurred, supported, as it were, by the right of private warfare, which in the last resort was the resource both of the lord to enforce obedience from the vassal, and the vassal to protect himself against his equal or his superior: on failure of heirs, the fief fell or escheated to the lord. Fiefs holden by military tenure were, strictly, *proper* fiefs. There were also a great variety of tenures by rendering particular stipulated services, created, for the most part, in

comparatively late times, which were also deemed feudal in their character, and constituted *improper* fiefs; such were, especially, tenures by the performance of menial or other personal services, from which arose the English *grand serjeanty* (which see). All these tenures were of a higher or noble character; but in some countries large portions of the land were held either immediately of the king, or mediately of feudal lords, by base or inferior tenures. Such lands were styled *fiefs roturiers* in French jurisprudence: in English, this class of tenures was comprehended under the common term of *socage*, which comprised both tenures in *free* or common socage, and those in *villein* socage, from which are derived tenures in *ancient demesne*. (*See* SOCAGE.)

The division of ranks under the feudal system corresponded in theory, although not precisely in practice, to the territorial division of lands according to their tenures. Those who held their fiefs by knight-service were the original nobility of the soil; nor has the class of gentry, in most countries, any other origin. The bearing of arms, the distinctive character of sirnames, &c. &c., became afterwards, in course of time, the distinctive marks of the class of nobility, which no longer adhered so closely to the soil from which it sprang. Thus in France we find that a noble might, in later times, hold a fief roturier, while a roturier might hold a proper fief; although, in such a case, services such as were rendered by the gentry were of course commuted. But it may be in general observed, that almost the whole soil of France, north of the Loire, was under noble tenures; in the south only were free tenants, not noble, — a numerous class. In many parts of Germany the distinction between *adeliche güter* (noble fiefs) and *bauer güter* (peasant fiefs) has only been recently effaced, or still subsists: in Prussia it was abolished in 1807. In England the course of the feudal system was somewhat different; the class of free tenants in socage was far more numerous and influential: hence the yeomanry of England formed a body of men to which a parallel could hardly be found in any other country. The burgesses, or inhabitants of towns, constituted in feudal realms a class apart; and their communities were either really, or by fiction, emancipated by royal charters from the tenure by which they were supposed to hold their land either of the king or some mesne lord. Lastly, the lowest class of the population consisted of serfs or villeins, attached to the soil in many instances; but whose state varied so greatly under different circumstances, as to render it impossible to give any general description of their condition.

Such is a very brief and general outline of the complicated system of rights and duties which bears the historical name of feudal. It is necessary, however, to add, that this system assumed very different shapes in the different countries in which it prevailed. 1. France was the country in which feudalism had, if not its origin, at least its greatest extension, and was most nearly reduced in practice to its theoretical form. Up to the fall of the Carlovingian empire, that country must be regarded as an aggregate of provinces, inhabited by different nations, and governed by a variety of laws, but acknowledging the sovereignty of a monarch whose power was more or less obeyed, according to his own personal talents and other casual circumstances. After the separation of France and Germany by the treaty of Verdun in 843, a succession of feeble princes and the invasions of the Normans almost broke up the slender frame of the French monarchy. The governors or masters of extensive provinces, who had by this time secured to themselves the hereditary sovereignty of their respective benefices, became independent within their own limits: when feudal royalty was continued under the Capetian kings, these ranked as the great vassals of the crown. Their powers have been classed (by Mr. Hallam) under five heads: 1. the right of coining money; 2. that of waging private war; 3. the exemption from all public tributes except the feudal aids; 4. the freedom from legislative control; and 5. the exclusive exercise of original judicature in their dominions: of these, the fourth was the most characteristic of the French system. No general legislative power, vested in an assembly of the nation, seems ever to have existed in France as a whole. This circumstance, which in the first instance seemed to the great vassals their independence, proved in the end the cause of their decay; as, with the gradual increase of the royal powers, the legislative authority of the king himself, in the absence of any recognized national council to assist him, acquired continually increasing force. Meanwhile, the extraordinary power of the great vassals in France in some degree weighed down that of the inferior nobility; the ties of feudal subjection, weakened in the highest relation (that between the great vassals and the crown), were much stronger between the great lords and the lesser barons, chatelains, or vavassors, who depended on them. The king, according to the establishments of St. Louis, could not declare any new law in the territory of his baron without his consent, neither could the baron in that of his vavassor; but, in a partial point of view, the king and the baron, within their respective demesnes, exercised a much more real sovereignty than that which the former possessed over the latter. It was about the reign of Philippe-le-Bel, in the beginning of the 14th century, that the feudal system, which had lasted up to that time from its establishment in the 10th without material innovation, was in effect overthrown, and that the king of France began to be in reality master of his kingdom. This change was chiefly brought about by the extension of the king's juridical power by means of the parliaments; and lastly by the convocation of the states-general, as the representative body of the whole nation: the greater fiefs were re-annexed in the course of events to the crown, with the remaining power and privileges of their lords. — 2. There can be no question that feudal principles prevailed to a considerable degree in the polity of the Saxons in England; but when that kingdom was conquered by the Normans they imported with them the entire system, already invested (in the 11th century) with a legal and regular character. Hence, while feudalism grew up from the circumstances of society in France, it may be said to have been transplanted, as to most of its details, into England from a foreign soil. The land was parcelled out, as in France, between higher feudatories and inferior tenants holding of them by knight-service. But two circumstances chiefly produced the very different shape into which the system ultimately resolved itself: 1. The existence of the great body of freemen of Saxon descent, who were neither reduced into villenage, nor deprived of their lands, nor yet ennobled by being ranked along with the Norman military tenants. 2 The permanent national council, which seems to have been every where a peculiarity of the Norman system of government, and which, by taking cognizance of matters pertaining to the general interests of the realm, at once controlled the power of the king and that of the great barons as single and independent chiefs. Thus the country remained, even in the most troubled period of the Plantagenet dynasty, in constant union under some central authority; and the feudal principles were modified, both by the common law of the land, and also by various statutes, of which that commonly styled by its first words "Quia Emptores," passed in the reign of Edward II. which put an effectual stop to all farther *sub-infeudation*, was perhaps the most effectual. — 3. In Germany, as well as France, the feudal usages seem to have grown into a system under the sovereignty of the Carlovingian emperors. But in that country, owing, perhaps, partly to the constant danger from foreign invasion on the eastern side, which kept the people more together under the central authority, the sovereigns never lost, during the dark period of the 9th and 10th centuries, so much of their power as those of France. Hence the greater vassals did not acquire such complete independence; but when, after the 11th century, the elective character of the empire was more fully recognized, the imperial power decayed; and that of the vassals rose during the period in which the contrary progress was taking place in France. And as the inferior barons had not been depressed, as in the latter country, by the overgrown power of the superior, Germany presented the example of a country in which the feudal system was carried out more completely, and for a greater length of time, into actual existence than any other; nor is there any in which the frame of society, to the present day, shows so many relics of its long predominance. — 4. In Italy the feudal system, under the Carlovingian government, was widely prevalent. The chief cause, in that country, which weakened and brought it to decay, or rather prevented its complete establishment, was to be found in the power and independence of the large towns, which at first effectually resisted, and afterwards broke down, the strength of the nobility. — 5. In Spain feudal tenures were of late introduction, and very partially known, except in the kingdom of Arragon. — 6. In the northern and eastern kingdoms of Europe (Sweden, Denmark, Hungary, Bohemia) they were never introduced at all, except in some few instances wholly without general effect.

FE'VER. (Lat. febris.) A disease, one of the most general symptoms of which is increased heat of the body. The temperature is often actually higher than it should be; and often the sensations of heat, dryness, and even burning of the skin, are excessive, independent of any proportional increase of thermometric heat. The subject of fever has given rise to an infinity of medical discussion and theory; and the definitions of the disease, given by different writers, are not less varied than numerous. In fevers there is generally great constitutional derangement, unaccompanied by local or perceptible organic disease. Fevers generally begin with languor of body and mind; chilliness, amounting to shivering, though the skin often at the same time feels hot; the pulse is quicker than it should be; respiration hurried or laboured; pains are complained of in various parts, and especially about the head, back, and loins; the appetite falls off, or there is nausea and vomiting; the mouth is dry; the bowels generally constipated; and the urine small in quantity and deep in colour. These, which constitute

the first stage of ordinary febrile symptoms, are succeeded by alternate flushings, a quicker and fuller pulse, rapid alternations of shivering and burning heat, and by mental anxiety and wandering, which, under a great variety of aspects and modifications, constitute the second stage: they are succeeded by the third stage, in which the leading appearances are a cleaner tongue, a more natural pulse, a moist skin, calm mind, and the urine becomes more copious in quantity, and deposits a sediment as it cools. The symptoms of fever generally undergo an increase every evening, which is called an *exacerbation;* and this fluctuation often takes place more than once in the twenty four hours, the violence of the attacks increasing with their occurrence, and forming what is called a *continued fever*. After some days, a *crisis* takes place; that is, the symptoms either take a favourable or an unfavourable turn. If the exacerbation and remission of symptoms are well marked, and occur once or oftener in the day, the fever is called a *remittent;* if the fever leaves the patient after some hours' duration, and returns at stated intervals, it is called an *intermittent*. (*See* AGUE.) Fevers are also variously denominated, according to the prevalent symptoms, as *inflammatory*, *typhus or putrid*, *nervous fever*, &c.; or according to cutaneous appearances connected with them, such as *scarlet fever* and *yellow fever*.

FIARS. A word of Gothic origin, signifying, in Scotland, the prices of grain for the current year in the different counties, fixed by the sheriffs respectively in the month of February, with the assistance of juries. The form of striking the fiars, says Mr. Bell, in his Law Dictionary, is prescribed by the Acts of Sederunt, Dec. 21. 1723, and July 29. 1728. A jury must be called, and evidence laid before them of the prices of the different grains raised in the county; and the prices fixed by the opinion of the jury, and sanctioned by the judge, are termed the *fiars* of that year in which they are struck, and regulate the prices of all grain stipulated to be sold at the fiar prices. The fiar prices also regulate the price in contracts concerning grain (the product of the county) to be delivered, and where no price has been otherwise agreed upon between the parties. Having the prices of grain, &c. ascertained in each county has greatly facilitated the introduction into Scotland of the practice of letting land for corn rents convertible at the prices of the day. In England, where there is no such authentic local returns, there is great difficulty in converting corn rents into money rents, inasmuch as reference can only be made to the prices in some particular market, or in the kingdom at large; the one of which is too limited, and the other too extensive. See *Bell's Law Dictionary*, and the authorities there referred to.

FI'AT. (Lat.) In Law, a short order or warrant of some judge for making out certain processes, &c.

FIAT In Bankruptcy. *See* BANKRUPTCY.

FI'BRE. One of the two bases of all vegetable structures. It may be compared to a hair in inconceivable fineness, its diameter often not exceeding $\frac{1}{1200}$ of an inch; also the name of the finer divisions of roots.

FIBRI'LLÆ. In Botany, the minute subdivisions of the root, each being a small bundle of annular ducts, or sometimes of spiral vessels incased in woody tissue covered by a lax cellular integument, and in direct communication with the vascular system of the root. The apex is composed of lax cellular tissue and mucus.

FI'BRIN. A term applied by chemists to the muscular fibre when cleansed by washing from all adhering impurities; or to the coagulum of the blood when the whole of the colouring matter is washed out of it. It is white, insipid, and inodorous; its ultimate elements are, according to Gay Lussac and Thenard,

Carbon	53·36
Hydrogen	7·02
Nitrogen	19·93
Oxygen	19·69

It is merely a form of *albumen*.

FI'BROLITE. A rare mineral of a peculiar fibrous texure, accompanying *corundum* from the Carnatic and from China.

FI'BULA. A long slender bone of the leg, placed upon the outer side of the tibia, the lower end of which forms the external ancle.

FICOI'DEÆ. A natural order of shrubby or herbaceous Exogens, inhabiting hot sandy plains. They are related to *Crassulaceæ*, *Chenopodiaceæ*, and *Silenaceæ*, and especially to *Cactaceæ;* but are distinguished by their embryo being curved round mealy albumen, a superior calyx, and perigynous stamens. The succulent leaves of some are eaten, while others yield soda.

FICTION. In Literature. *See* NOVEL, ROMANCE.

FICTION OF LAW, has been defined, by writers on the civil jurisprudence, to be an assumption of the law upon an untruth in something possible to be done but not done. The utility of such fictions is merely, by substituting the imaginary for the true state of the case, to [...]ore rapidly over those parts of the subject which are not disputed, and arrive at the points really in issue. Among the more notorious fictions of the English law may be noticed the course of proceedings in the action of ejectment, in which an imaginary tenant brings his complaint of having been turned out of possession by a wrongdoer, in order to try the validity of the title of the landlord: that of a common recovery, by which estates tail were bound through a complicated proceeding (removed by recent statutes, *see* FEE-TAIL), consisting of an imaginary suit at law. The general rule is, that such fictions are not traversable; *i. e.* cannot be contradicted by him against whom they are used, so as to defeat the end for which they are invented. And for the same purpose the court will take notice that they are only fictions, if necessary, in order to prevent mere technical objections to them.

FID. A short bar of wood or iron put through the heel or lower part of a topmast, and resting by its ends on the trestle-trees, and on which the mast is therefore supported. When the topmast is to be got down, it is first lifted to take the pressure off the fid, which is then withdrawn.

FID, or SPLICING FID, is also a sharp cone of wood for opening the strands of rope.

FI'DEI COMMI'SSUM. (Lat. *committed or entrusted to faith.*) A species of testamentary disposition recognized by the Roman law, by which a testator, in indirect terms, charged his heir to deliver over to a specified person the whole or a part of the goods which he inherited. Fidei commissa were usually adopted as a means of bequeathing property to persons legally incapable of directly receiving the bequest. Fidei commissa were, as their name implies, at first dependent entirely on the faith of the heir for their execution; but that execution was rendered compulsory by Augustus in some cases; and this became afterwards the general law, the heir being, however, entitled, where he voluntarily accepted the testament and charged himself with its execution, to retain one fourth of the property entrusted to him for delivery.

FIDE JU'SSOR. In the Civil Law, one who engages himself for the debt of another, promising to pay in case the original debtor should make default: who is called in the law of England a *guaranter*.

FIEF. (Lat. feodum.) The French name for an estate in lands held of a feudal superior. In English law language, a *fee:* also termed a *feud* by writers on feudal jurisprudence. (*See* FEUDAL SYSTEM.) In the legal language of France, a *fief* was opposed to an *aleu*, or estate held allodially, without any lord paramount. Various derivations of the word have been given; but the most probable is that which traces it through the steps feodum, feudum, emphyteuticum, from the Gr. ἐμφυτευσις, a contract whereby the use of the land without the property in it was surrendered to a tenant.

FIELD. In Agriculture, a portion of land enclosed by a fence, or rendered distinct by some line of separation, so as to adapt it for culture. In former times, and until within the last two centuries, almost all the land cultivated with the plough throughout Europe was unenclosed; and the term field was then applied, in Britain at least, to the lands under culture by the plough. Subsequently, when farmers enclosed and subdivided a portion of the lands near the farm yard, these portions were called fields; and the more distant portion which remained open was called open field, or common field; while grass lands unenclosed were called commons. In the present improved state of agriculture, every farm is divided into fields, either simply by lines of demarcation, which are sufficient when no animals are to be grazed on the farm; or by lines of separation which will act as fences, such as walls, hedges, ditches, &c. where cattle are to be grazed. Without some regular fixed division of arable lands, it would be next to impossible to conduct a rotation or succession of crops. It is interesting to observe that as agriculture in a rude state had no fences, so this is also beginning to be the case in agriculture in its most refined form; because it is found much more advantageous, both for the production of butcher's meat and manure, to consume the grass and herbage grown on farm lands in farm yards, with the single exception of that portion which is eaten by sheep; and these are confined to successive portions of grass land by light netting hurdles, scarcely visible at a short distance. By thus getting rid of fences of every description, from a tenth to a fifth will be added to the contents of the greater number of corn farms; and a very considerable first cost and annual expense will be saved in planting hedges or building walls, and in keeping them in repair afterwards.

FIELD. In Heraldry, the tincture, or combination of tinctures, which forms the ground of the escutcheon on which the device or charge is delineated. *See* TINCTURE.

FIE'LDFARE. A bird of the thrush tribe (*Turdus pilaris*, Linn.), which is a seasonal visitant in this island. It makes its appearance about the beginning of October, migrating from the colder northern parts of the Continent in flocks, numerous according to the severity of the

season. They fly in a body; and if alarmed when dispersed over a field in quest of food, they collect together as they fly off, and often settle in a swarm on the same tree. They leave us about the latter end of February, or the beginning of March; and retire to breed in Sweden, Norway, Russia, and the northern parts of Asia as far as Kamtschatka.

FIELD LARK. *See* LARK.

FIELD MA'RSHAL. The highest military title in this and some other countries. It is conferred only on officers distinguished for brilliant military services or exalted station. The term is derived from the *maréchal de camp* in the old French service, and was long in use among the Germans in its present distinguished acceptation before it was adopted in this country. There are at present only five field marshals in the British army; the Duke of Wellington, the King of Hanover, the Duke of Cambridge, the King of Belgium, and Prince Albert.

FIELD OF VIEW, in a telescope or microscope, is the space within which objects are visible when the instrument is adjusted to focus.

FIE'LDVOLE. A name of the short-tailed field-mouse, or meadow-mouse (*Arvicola agrestis*, Cuv.). A species which subsists exclusively on vegetable productions; and being, like the rest of the rat tribe, extremely prolific, multiplies occasionally to such a degree, even in this country, as to become the most injurious of our wild quadrupeds. "After having followed the labours of the reaper, and taken their share of the harvest, the fieldvoles," says Mr. Bell, "attack the newly sown fields, burrowing beneath the surface, and robbing the husbandman of his next year's crop; and at length, retreating to the woods and plantations, commit such devastations on the young trees as would scarcely be credible, were not the evidence too certain to be doubted. In the years 1813 and 1814 these ravages were so great in the New Forest and the Forest of Dean, as to create considerable alarm lest the whole of the young trees in those extensive woods should be destroyed by them." A timely and assiduous attention to restraining the increase of this pernicious species by the aid of terriers, ferrets, and traps, is imperative on those who have the charge of young plantations; but when the numbers of the fieldvole have surpassed the usual bounds, then it is recommended to dig holes about a foot in depth, and the same in diameter, taking care to make them much wider at the bottom than at the top, so that the animal when once in cannot easily get out again. In holes of this kind Mr. Jesse states that at least thirty thousand fieldvoles were caught, in the course of three or four months, in Dean Forest plantations; that number having been counted out and paid for by the proper officers of the forest.

FI'ERI FACIAS. In Law, a judicial writ, that lies where judgment is had for debt or damages recovered in the king's courts; by which writ the sheriff is commanded to levy the debt and damages of the goods and chattels of the defendant. This writ is to be sued out within a year and a day after judgment; or the judgment must be revived by *scire facias*.

FIFE (Germ. pfeiffe.) A small wooden musical wind instrument of the flute species played by holes, exceedingly shrill in tone, and rarely used except in military bands.

FIFTEENTH. In Music, an interval of two octaves; also a name given to a stop on the *organ*, a double octave above the diapason, as its name imports.

FIFTH. In Music, one of the harmonical intervals or concords. It is the second in order of the concords, the ratio of the chords that afford it being as 3 : 2. It is called the fifth, as containing five terms or sounds between its extremes and four degrees; so that in the natural scale of music it comes in the fifth place or order from the fundamental. The ancients called it *Diapente*, and the Italians at present call it *Quinta*. The *imperfect*, *defective*, or *false fifth*, called by the ancients *semi-diapente*, is less than the fifth by a lesser semitone.

FIFTH-MO'NARCHY-MEN. A fanatical sect, who formed a principal support of Cromwell during the Protectorate. They considered his assumption of power as an earnest of the foundation of the fifth monarchy, which should succeed to the Assyrian, the Persian, the Grecian, and the Roman, and in which Jesus Christ should reign with the saints on earth for the space of a thousand years. Upon the restoration of the royal family, and the return of the kingdom to its former principles in church and state, a party of these enthusiasts, headed by a man of the name of Venner, made a desperate insurrection in the streets of London, which was put down with the slaughter of a great number of them.

FIGS (Lat. ficus, *a fig tree*), are the fruit of a small tree with broad-lobed leaves, inhabiting the south of Europe and similar latitudes in Asia. This fruit is not of the same nature as the apple, the orange, and other fleshy seed-vessels; but is a hollow receptacle, containing a great multitude of minute flowers, the ripe fruit of which is the seed, as it is wrongly called, that is imbedded in the pulp. It is remarkable that the fig tree, although it produces so agreeable a fruit, is in some measure poisonous, its milky juice being acrid to the taste, and of the same nature, although less intense, as that of certain Indian species called *F. toxicaria*, *Dæmonum*, &c., because of their venomous qualities. The genus *Ficus* itself is of considerable extent, and its species are among the most noble objects belonging to the vegetable kingdom in tropical countries, where they often yield caoutchouc of the finest quality. *Ficus elastica* is particularly valuable for this purpose, as are also various unknown species in the island of Java. The banyan tree, so celebrated for the large extent of ground covered by single individuals, which carry an enormous canopy of branches and leaves upon columnar trunks provided for the purpose as the tree advances in diameter, is a kind of fig tree, *Ficus religiosa*.

FIGURATE COUNTERPOINT. In Music, that which contains a mixture of discords together with the concords.

FI'GURATE NUMBERS. In Arithmetic, the name given to series deduced from any progression by differences of which the first term is unity and the ratio a whole number, by taking successively the sum of the two first, the three first, the four first, &c. terms of the progression; and then operating on the new series thus obtained in the same manner as on the original progression, in order to obtain a second series, and so on.

For example, let the progression be that of the natural numbers, the common difference of which is 1; then the progression and the different series of figurate numbers successively deduced from it are as follows:—

A. . .	1,	2,	3,	4,	5,	6,	7,
B. . .	1,	3,	6,	10,	15,	21,	28,
C. . .	1,	4,	10,	20,	35,	56,	84,
D. . .	1,	5,	15,	35,	70,	126,	210.

The first line, A, is the progression from which the series arises. The second line, B, is the series of *triangular numbers*, or *polygonal* numbers of the first order. Its formation is obvious, each term being the sum of the corresponding and all the preceding terms of the progression; whence, by the theory of series, its general term is,

$$\frac{n(n+1)}{1 \cdot 2}.$$

The third line, C, is the series of triangular pyramidal numbers, and is formed from B in the same manner as the latter was formed from A. Its general term is,

$$\frac{n(n+1)(n+2)}{1 \cdot 2 \cdot 3}.$$

The fourth line, D, is formed from C in the same manner as C from B, or B from A. Its general term is,

$$\frac{n(n+1)(n+2)(n+3)}{1 \cdot 2 \cdot 3 \cdot 4}.$$

If the original progression be,

1, 3, 5, 7, 9, 11,

the common difference of which is 2; then the series of figurate numbers successively derived from it are,

1, 4, 9, 16, 25, 36,
1, 5, 14, 30, 55, 91, &c.

The first of these is the series of square numbers, the second that of quadrangular pyramidal numbers. In like manner, if the common difference of the assumed progression be 3, then the successive sums will be the series of pentagonal numbers; if it be 4, the sums will give the hexagonal numbers, and so on. The formation of these different orders of figurate numbers will be readily understood from inspection of the following table:

Progressions.	First sums, or polygons of the first order.	Second sums, or polygons of the second order.
1, 2, 3, 4	Tri. 1, 3, 6, 10	1, 4, 10, 20
1, 3, 5, 7	Sq. 1, 4, 9, 16	1, 5, 14, 30
1, 4, 7, 10	Pent. 1, 5, 12, 22	1, 6, 18, 40
1, 5, 9, 13	Hex. 1, 6, 15, 28	1, 7, 22, 50

The names triangular numbers, squares, pentagons, hexagons, &c., have been applied on account of certain analogies which the numbers so denoted have with the geometrical figures bearing the same denominations. Thus, in the second column of the above table, which contains the polygons of the first order, the terms forming the first line or series express the different numbers of points which may be placed at equal distances, so as to form an equilateral triangle. The second line or series gives the different numbers of points which may be arranged in squares, the third those which form regular pentagons, the fourth those which form regular hexagons, and so on. In the third column of the table, the first series contains the several numbers of points which may be so disposed as to form a triangular pyramid, the second those which form a quadrangular pyramid, and so on.

The different series formed as above possess several curious properties, of which one of the most remarkable

is, that the general term, and the sum of any number of terms n, can always be expressed rationally in terms of n. In fact, the expression of the nth term of any series is the same as that of the sum of the n first terms of the series immediately preceding it, or from which it is immediately derived.

FI'GURE, in Rhetoric, has been defined, generally, as a mode of speech in which words are changed from their literal and primitive sense. It is almost impossible to give, within the limits of a definition, the precise and numerous meanings of which this term is susceptible; but under the separate heads, such as ANTITHESIS, METAPHOR, &c., will be found a notice of the different figures used in composition. In Logic, the word figure is applied to the form of a syllogism with regard to the disposition of the middle term. *See* TROPE.

FIGURE, in Geometry, is used in two different senses. In the first sense, it denotes, generally, a space bounded on all sides, whether by lines or by planes; in the second sense, it signifies the representation (on paper for example) of the object of a theorem or problem, in order to render the demonstration or solution more easy to be understood and followed. In this last sense, *figure* is synonymous with *diagram*.

All bodies are necessarily enclosed by one or more boundaries, and therefore possess figure: hence *figurability* is reckoned one of the essential properties of matter.

For *Figure of the Earth*, see EARTH and DEGREE; for *Figure of the Planets*, see PLANET.

Apparent Figure, in Optics, is the figure under which an object presents itself to our view. This depends on the situation of the points from which rays of light pass to the eye of the spectator, and may be very different from the real figure of the object; for a straight line, when placed in a particular direction, will be seen only as a point, a plane as a straight line, and a solid which presents only one of its faces will appear as a simple surface. (PERSPECTIVE.)

FIGURE HEAD. The figure, statue, or bust, on the projecting part of the head of a ship, called the cutwater.

FIGURES, in Arithmetic, are the numeral characters, or ten digits, by which numbers are expressed. They are supposed to be of Indian origin, and to have been introduced into Europe by the Moors of Spain in the 13th century; but the date of their introduction is much disputed. (ARITHMETIC.)

FI'LACER, or FI'LAZER. (Fr. fil, *thread.*) An officer of the court of Common Pleas, who files writs. The filacers (of whom there are fourteen) are mentioned as early as the stat. 10 H. 4. There are also filacers of the Queen's Bench.

FI'LBERT, or FILBERD, the well-known fruit of the cultivated hazel nut, or *Corylus avellana*, is a seed-vessel enclosed within an involucre or cupule, which is the part commonly called the husk. This organ is of the same nature as the cup of the oak, and the prickly case in which the nuts of the sweet chestnut and the mast of the beech are enclosed. In the filbert it is much larger than in the common nut; and it is this character, together with the lengthened figure of the nut, which distinguishes the two races of nuts and filberts, each of which abounds in varieties. The best known varieties of the filbert are the red, the frizzled, and the white, the latter being the kind most commonly grown in this country.

FILE. (Germ. feile.) This instrument is formed by cutting teeth upon a plate or tool of soft steel by the repeated blows of a straight-edged chisel. These teeth either form a single series of straight lines, or they are crossed by a second series; the former are called *single cut*, the latter *double cut* files. Files are required to be extremely hard; and unless they are carefully and skilfully hardened, they are apt to warp. The best files are made exclusively of cast steel, and are cut by hand, none of the file-cutting machines producing unexceptionable tools.

FI'LIFORM. (Lat. filum, *a thread.*) In Zoology, when a part is slender, thread-shaped, and of equal thickness.

FILL. The sea term for bracing a yard which had been laid aback, so that the wind may act on the after or proper side of the sail.

FI'LLET. (Fr. filet.) In Architecture, a small square member placed above or below other larger members in an order. The term as used by carpenters and joiners means a small piece to which boards, joists, or quarters are nailed.

FI'LLIGRANE, or FILLI'GREE. (Lat. filum, *thread.*) In Sculpture, an extremely fine ornamental work of flowers, fruits, &c., formed with gold or silver wire in serpentine layers, or plaited and worked otherwise together and soldered. It is an eastern invention.

FILO'SE. (Lat. filum.) In Zoology, when a part ends in a thread-like process.

FILTRA'TION. (Lat.) The process by which liquids are separated from substances mechanically suspended in them; it is also sometimes resorted to to separate colouring matters and other bodies which are in a state of solution, and which are removed by the substance or matter through which the liquids are filtered. Unsized paper is commonly used in the chemical laboratory for the former purpose, and is known under the name of filtering paper; it is properly folded, and placed for support in a glass funnel. In the arts, linen and calico bags of different forms are frequently employed, containing well-burned charcoal or other materials, through which the liquids requiring purification are suffered slowly to trickle. In *water filters*, the coarser particles are generally collected in a piece of sponge, and the further separation of the more finely divided matters or organic taints is effected by layers of sand of various degrees of fineness mixed with a proper quantity of charcoal. (See *Faraday's Chemical Manipulation;* and *Ure's Dict. of Arts, &c.*)

FIN. (Lat. finna.) A flattened expanded organ, projecting from the body, and serving as an instrument of locomotion in water.

Many species of the whale tribe possess an immoveable fin upon the back, composed merely of a reflection of integument over a mass of dense and ligamentous cellular membrane; the tail fin in the same order has a similar structure, but is moved by the action of the muscles upon the caudal vertebræ, which are continued through the middle part. The anterior fins, corresponding to the pectorals in fish, are susceptible of greater variety of motion, from being supported by a series of bones corresponding to those of the fore extremity of other mammalia. In fishes the fins are supported by elongated filamentary bones or rays, the nature and number of which afford the zoologists important characters for distinguishing the different groups; and in works of Ichthyology a system of notation is employed, which briefly but clearly expresses these characters. Thus the formula of the number of fin-rays in the perch is thus expressed:—

$$D.\ 15, 1 + 13;\ P.\ 14;\ V.\ 1 + 5;\ A.\ 2 + 8;\ C.\ 17.$$

Which signifies that D., the dorsal fin, has in the first fin 15 rays, all spinous or bony; in the second fin, 1 spinous plus 13 that are soft. P., pectoral fin, 14 rays, all soft. V., the ventral fin, with 1 spinous ray plus 5 that are soft. A., the aural fin, with 2 spinous rays plus 8 that are soft. C., the tail or caudal fin, 17 rays. In enumerating the rays, those only which extend from the longest ray in the upper portion to the longest ray in the lower portion, both inclusive, are counted.

FINA'LE. (It.) In Music, the last of a series of movements in a composition; also the closing scene of each act of an opera buffa.

FINA'NCE. The revenues of a king or state. The word is derived by some from the German *finanz;* by others from the barbarous Latin word *financiatio*, a loan.

FINCH. *See* FRINGILLIDÆ.

FINE, in Law, as a punishment, is a pecuniary mulct or amende imposed by a competent jurisdiction. The party thus mulcted for offences against a feudal superior was said, in the language of that jurisprudence, "finem facere de transgressione cum rege, domino," &c., to *make an end* of his offence: whence the word is derived. Fines are in no case determined as to amount by common law, and seldom by statute, except as to their maximum; but by the general cautions of Magna Charta and the Bill of Rights, excessive fines ought not to be imposed. Courts of record have in general the power of imposing fines in case of contempt, and also on conviction of offences punishable in this manner. The mode of returning, estreating (*i.e.* entering on the rolls of a court), and levying fines is now regulated by 3 & 4 W. 4. c. 99.

FINE OF LANDS. In Law, a species of conveyance or record for the settling and securing lands and tenements, now abolished by stat. 3 & 4 W. 4. c. 74.; although, as long as questions can still arise on the validity and effect of fines levied before that period, the legal doctrines respecting it cannot be said to be wholly obsolete. A fine was, in its original signification, an agreement or composition of a suit (whether real or fictitious) made between demandant and tenant in respect of lands and tenements, with the consent of the judges, and enrolled among the records of the court. Hence, by a common fiction, such an imaginary agreement was employed in certain cases as a mode of conveyance. Its chief properties were,—the extinguishment of dormant titles by barring strangers (unless they claimed within five years, under 1 Ric. 3. c. 7.); and, when levied of an estate in tail, the barring the issue in tail immediately, but not those in remainder or reversion, except when tenant in tail had such reversion in himself. A fine was effected with certain solemnities, as the termination of an imaginary action at law. The party conveying was termed the cognisor or conusor, the party to whom conveyance was made the cognisee of the fine. A fine, besides its peculiar properties in the settlement of lands held in tail, was the usual method whereby a feme covert joined in the sale, settlement, or incumbrance of an estate; for which, by the stat. 3 & 4 W. 4. above mentioned, a peculiar deed is substituted, to be executed and acknowledged by the married woman after examination by commissioners.

FINE'SSE (Fr.), may be defined simply as a peculiar aptitude of discovering, in any business, the best means of attaining the object in view ; or as the power of embracing in one comprehensive glance the various interests of any subject, together with ingenuity to devise and tact to carry out the plan best calculated to obtain success.

FINE STUFF. In Architecture, plaister used in common ceilings and walls for the reception of paper or colour. It is composed of lime, slaked and sifted through a fine sieve, then mixed with a due quantity of hair and fine sand. A mixture of lime and hair, used in the *first coat* and floating of plastering, is called *coarse stuff.*

FI'NGER BOARD. In Music, the black board attached to the neck of instruments of the viol class, on which the strings are pressed by the fingers for the purposes of adjusting their lengths so as to produce the different sounds.

FI'NGERING. In Music, the art of arranging the fingers on instruments of all classes, so that they may be in the best positions for performing the different passages written for such instruments.

FI'NIAL. (Lat. finis, *the end.*) In Gothic Architecture, the top or finishing of a pinnacle or gable, as it is now generally understood ; but in ancient documents an entire pinnacle is understood by this term.

FI'NISH. (Lat. finire, *to end.*) In the Fine Arts, the last working up of any object of art, whereby its completion is effected.

FI'NISHING COAT. In Architecture, the best coat of stucco work when three coats are used. When in the third coat fine stuff is used for paper, it is called setting.

FI'ORITE. A siliceous incrustation, from *Fiora* in Ischia.

FIRE. *See* FLAME and HEAT.

FIRE BALLS (called also *Bolides*, and *Fiery Meteors*), in Meteorology, are luminous bodies which suddenly appear in the sky, usually at a great height above the earth, and shoot through the heavens with immense velocity, and are sometimes accompanied with the fall of an aërolite. These meteors are of frequent occurrence, and numerous descriptions of their appearances at different times are to be found in the *Transactions of the Royal Society ;* but by far the most remarkable apparition of the kind on record, is that which was observed in America on the 13th of November, 1833, and is described in vols. xxv. and xxvi. of the *American Journal of Science*, and also the *American Almanac* for the year 1835. We will give a brief abstract of the relation, which is of extreme interest ; not only on account of the extraordinary nature of the appearances, but also as it seems to indicate that these phenomena, hitherto but little heeded, may serve to make us better acquainted with the constitution of the planetary system.

"The meteors began to attract notice by their frequency as early as nine o'clock on the preceding evening (Nov. 12.) ; the exhibition became strikingly brilliant about eleven, but most splendid of all about four o'clock ; and continued with but little diminution until merged in the light of day. A few large fire balls were seen even after the sun had risen. The entire extent of the exhibition is not ascertained, but it covered no inconsiderable portion of the earth's surface. It has been traced from the longitude of 61° in the Atlantic Ocean, to longitude 100° in central Mexico, and from the North American lakes to the southern side of the island of Jamaica. Every where within these limits the first appearance was that of fire-works of the most imposing grandeur, covering the entire vault of heaven with myriads of fire balls resembling sky-rockets. On more attentive inspection, it was seen that the meteors exhibited three distinct varieties ; the first consisting of *phosphoric lines*, apparently described by a point ; the second, of large fire balls, that at intervals darted along the sky, leaving luminous trains, which occasionally remained in view for a number of minutes, and in some cases for half an hour or more ; the third, of undefined luminous bodies, which remained nearly stationary for a long time.

"One of the most remarkable circumstances attending this display was, that the meteors all seemed to emanate from one and the same point. They set out at different distances from this point, and proceeded with immense velocity, describing in some instances an arc of 30° or 40° in less than four seconds. At Poland, on the Ohio, a meteor (of the third variety) was distinctly visible in the north-east for more than an hour. At Charleston, South Carolina, another of extraordinary size was seen to course the heavens for a great length of time, and then was heard to explode with the noise of a cannon. The point from which the meteors seemed to emanate, was observed by those who fixed its position among the stars to be in the constellation Leo ; and, what is very remarkable, this point was *stationary* among the stars during the whole period of observation ; that is to say, it did not move along with the earth in its diurnal rotation eastward, but accompanied the stars in their apparent progress westward. It is not certain whether the meteors were in general accompanied by any peculiar sound. A few observers reported that they heard a hissing noise like the rushing of a sky-rocket, or slight explosions like the bursting of the same bodies. Nor does it appear that any substance reached the ground which could be clearly established to be a residuum or deposit from the meteors. A remarkable change of weather from warm to cold accompanied the meteoric shower, or immediately followed it, in all parts of the United States."

The particulars which have been stated afford data for entering on the explanation of these mysterious phenomena. And, first, as the meteors appeared to emanate from a point which did not follow the earth's rotation, it is clear that they had not their origin in the atmosphere, but in the regions of space beyond it. The next question that occurs is, what was the distance from the earth of the region of space in which they had their origin ? It was ascertained that observations made in different latitudes indicated a corresponding parallax in declination ; and these observations being collected and carefully compared, gave an average distance from the surface of the earth of 2238 miles as the height of the meteoric cloud. This estimate must be regarded only as an approximation,—the best, however, that could be derived from data that are imperfect and often discordant. Assuming this result to be nearly correct, it is easy to compute the velocity with which the meteors would enter the atmosphere. A body falling from a height of 2238 miles by the attraction of gravity alone would acquire, at the distance of fifty miles from the earth (the supposed height of the atmosphere), a velocity of *four miles per second*, which is more than ten times the velocity of a cannon-ball. The meteors, therefore, on entering the atmosphere, would produce a sudden and powerful compression of the air before them. But when air is suddenly compressed, a great quantity of heat is extricated from it. In the present case, the heat would produce in the falling bodies an intense ignition ; and, if they were combustible, set them on fire. On submitting the subject to accurate calculation on established principles, it is ascertained that the quantity of heat extricated from the air by the falling meteors exceeded that of the hottest furnaces, and can only be compared to those immeasurable degrees of heat produced in the laboratory of the chemist. And this supposes the meteors to have entered the atmosphere with only the velocity due to the earth's attraction ; but if we suppose that they had also a relative velocity arising from the earth's motion towards them, they might then enter the atmosphere with a velocity of fourteen instead of four miles per second. In this case, the heat extricated from the air would be proportionally augmented. It is evident that the meteors must have been constituted of very light materials ; for, had their quantity of matter been considerable, with so prodigious a velocity they would have had sufficient momentum to reach the earth, and the most disastrous consequences might have followed. From the apparent magnitude of many of the meteors, and their probable distance, it was conjectured that they were bodies of very large size, though of course it is impossible to fix the limits of their magnitude with any certainty. Those masses were only stopped in the atmosphere, and prevented from reaching the earth, by transferring their motion to columns of air, large volumes of which would be suddenly and violently displaced. Now it is a remarkable fact, that the state of the weather, and the condition of the seasons following the meteoric shower, corresponded to those consequences of the disturbances of the atmospheric equilibrium. It is from the great and sudden changes of temperature caused by phenomena of this kind that the greatest danger is to be apprehended.

Theory of Fire Balls.—Various hypotheses have been proposed to account for these remarkable phenomena. In general, they have been regarded as meteors having their origin in the atmosphere ; and electricity, magnetism, hydrogen gas, have in turn been assigned as their immediate causes. Others again suppose them to be products of *nebulous* matter (perhaps of the same nature as the tails of comets), floating in the planetary regions, and which, when it happens to lie near the path of the earth in its revolution about the sun, will be attracted by terrestrial gravitation. The parallax of the meteors of 1833 indicates, as we have seen, that they proceeded from a point far beyond the limits of the atmosphere. The attentive examination of the circumstances of their appearances leads to other indications of a very remarkable nature. On projecting a diagram to represent the respective planes of the earth in its orbit, and the plane of the body from which the meteors proceeded, it appears that the earth was moving almost directly towards the meteoric body. Now the meteoric cloud remained apparently at rest, and of course nearly in the earth's path, for at least two hours. This could not have happened unless it had been moving nearly in the same direction as the earth, and with nearly the same angular velocity round the sun ; for had it been at rest, the earth, carried forward at the rate of 19 miles per second, would have

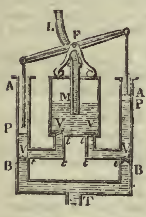
overtaken it in less than two minutes; and had the angular velocities of the two bodies not been nearly equal, they could not have remained so long apparently stationary with respect to each other. Hence it is inferred *that the body which afforded the meteors was pursuing its way with the earth round the sun.*

But supposing there is a body, or, which is more probable, a zone composed of myriads of little bodies, whose orbits intersect the plane of the ecliptic, is it not probable the earth must encounter some of them every time it passes through the point of intersection? A more attentive observation of these meteors than has yet been bestowed on them is perhaps necessary to solve this question. At present the following facts have been collected: — On the 12th of November, 1799, at Cumana, in South America, thousands of meteors or falling stars were seen to succeed each other during four hours. Of this exhibition an account is given by Humboldt and Bonpland. On the 13th of November, 1831, M. Berard, commander of the French brig Loiret, then off the coast of Carthagena in Spain, saw a great number of shooting stars and luminous meteors of large size. During more than three hours there occurred, on the average, at least two a minute. One of these meteors, which appeared near the zenith, in leaving an enormous train in the direction from east to west, presented a very large luminous band (equal to half the diameter of the moon), in which several of the colours of the rainbow were distinctly exhibited. Its trace remained visible during more than six minutes. (Arago, *Annuaire* for 1836.) On the 13th of November, 1832, remarkable exhibitions of meteors were seen at Mocha in Arabia; and on the 19th of the same month in various parts of England. On the 13th of November, 1835, a large and brilliant meteor fell near Belley, in the department of the Ain, in France, and set fire to a barn. On the same night a shooting star, larger and more brilliant than Jupiter, was observed at Lille by M. Delezenne; and, what is very remarkable, a number of extremely brilliant meteors were seen also on the same night, by Sir John Herschel and his assistant at the Cape of Good Hope, who, apprized of the phenomena that had been observed in America, were looking out for their appearance. The attention of observers being now generally called to the subject, the lapse of a few years will probably decide the question, whether the recurrence of the meteors on the same day of the year has been merely accidental; or a stream of nebulous matter has a temporary or permanent existence in that part of space through which the earth passes in its annual revolution, about the 13th of November. (*See* AEROLITE, SHOOTING STARS.)

FIRE BLAST. A term of very doubtful meaning, like the word blight. In Agriculture it is sometimes applied to plants which are suffering from the mildew fungi, or from minute insects; but its legitimate use would appear to be applicable only when the delicate parts of plants are too suddenly exposed to a brilliant sun, and the rapid transpiration which takes place in consequence dries up and shrivels their leaves.

FI'RE DAMP. The carburetted hydrogen gas of coal mines.

FIRE ENGINE. This most useful machine is constructed in a variety of forms, which all, however, agree in one principle. It generally consists of a double forcing pump communicating with the same air vessel; and instead of a force-pipe a flexible leathern hose is used, through which the water is driven by the pressure of the condensed air in the air vessel. The annexed diagram represents a section of the apparatus. The pipe T descends into a receiver or vessel containing a supply of water. This pipe communicates with two suction valves V, which open into the pump barrels of two forcing pumps A, B, in which solid pistons P are placed. The piston rods of these are connected with a working beam F, elongated so that a number of persons may work at both ends of it at once. Force-pipes *t*, *t*, proceed from the sides of the pump barrel above the valves V, and they communicate with an air vessel M, by means of forcing valves V, which also open upwards. The pipe descends into the air vessel near the bottom. This pipe is connected with the flexible leathern hose L, the length of which is adapted to the purposes to which the machine is to be applied. The extremity of the hose may be carried in any direction, and may be introduced through the doors and windows of buildings. By the alternate action of the pistons, water is drawn through the suction valve, and propelled through the forcing valves, until the air in the top of the vessel M is highly compressed. The pressure acts on the surface of the water in the vessel, and forces it through the leathern hose in a continued stream, so as to spout from its extremity with a force depending partly on the degree of condensation, and partly on the elevation of the extremity of the hose above the level of the engine. It is to be considered that the pressure of the condensed air has, in the first instance, to support a column of water, the height of which is equal to the level of the end of the tube above the level of the water in the air vessel; and until the pressure exceeds what is necessary for this purpose, no water can spout from the end of the hose; and, consequently, the force with which it will so spout will be proportional to the excess of the pressure of the condensed air above the weight of the column of water, whose height is equal to the elevation of the end of the hose above the level of the water in the air vessel. (*Cabinet Cyclopædia*, "Hydrostatics and Pneumatics," p. 326.)



The fire engine has received various improvements from Bramah, Dickenson, Simpkin, Raventree, Philips, and others. The above description applies to Newsham's engine. Braithwaite's *steam fire engine* is an application of the power of steam to the working of the fire engine. The mechanical arrangement consists of two cylinders of about six inches in diameter, one of them being the steam cylinder, and the other the water pump; and they are placed horizontally, so that a parallel motion is easily produced. This engine will deliver 9000 gallons of water an hour at the height of 90 feet. The time of getting the machine into action, from the time of igniting the fuel (the water being cold), is only 18 minutes. Some of the Fire Insurance Companies in London have floating engines on the Thames, which are extremely serviceable in cases of fire among the shipping or buildings near the river.

FIRE ESCA'PE. Any machine or apparatus for the purpose of enabling persons to escape from the upper stories of houses on fire. The contrivances which have been proposed for accomplishing this desirable object are very numerous, and are of two kinds; the first kind comprising those by means of which the escape is effected without external aid, and the second those requiring the assistance of persons without. Of the first kind the most obvious is a rope ladder, which may be kept in a sleeping apartment, and used upon occasion by fastening one end of it to a window-sill or bed-post. Mr. Maseres contrived an apparatus which consists of a long rope and an assemblage of cordage or belts, so disposed as to form a seat; the person about to descend binds himself into the seat, and then lowers himself to the ground by allowing the rope which is fastened to the window-sill to slide slowly through his hands; and in order that this may be done easily, the rope is made to pass through a series of holes in a block. But unfortunately contrivances of this kind can rarely be expected to be of any use; for supposing them at hand when the alarm of danger is given, few persons can command the coolness and attention which are requisite for fixing and adjusting the apparatus; and even then it is only the strong and active who could safely descend by such means from a considerable height.

With regard to escapes of the second kind, the object is to enable persons without to establish speedily a communication with an upper room, so as to afford the inmates the means of safe descent; or to remove them if necessary, as in the case of the feeble or children. A very portable sort of ladder, invented by Mr. Young, is described in the *Transactions of the Society of Arts* for 1813. It consists of a number of cross bars or rounds, connected with ropes, which form the sides of the ladder; the ends of the rounds are fitted into each other, so as to form a pole, which is readily elevated to a window; and at the extremity is an iron frame terminating in hooks which can be lodged in the window-sill. When the hooks are properly fixed, a sudden jerk suffices to separate the rounds, which immediately fall into their places when the ladder is formed and suspended from the frame. But this apparatus only answers the same purpose as a rope ladder, and is therefore liable to the same objections. Mr. Braby's fire escape, described in the 34th vol. of the same Transactions, consists of a car or cradle, which is made to slide on a slip of plank fixed to a pole, and is governed by a rope. Mr. Ford's escape consists of a spar of timber about 35 or 40 feet long, having two projecting arms at the top furnished with prongs, by which a firm bearing against the wall of a house is obtained. A grooved pulley is mortised into the spar near the top, and another near the bottom; over the pulleys runs an endless rope, to which is attached at one point a main rope, and at another the semicircular brace of a large grooved roller, which traverses up and down the space between the pulleys. This brace carries on the under side of the spar a hook, to which a cradle is attached, whereby persons can be easily lowered to the ground.

For a description of various other contrivances of a similar kind, we refer to the *Transactions of the Society of Arts* above quoted.

FI'RE FLY. A name commonly given to those insects which have the singular property of emitting a luminous secretion. This power is not confined to insects of one organization or order. Among the Coleoptera, the *Elater noctilucus* and the female glow-worm are conspicuous examples. The *Fulgoridæ*, or lantern and

candle flies, are also described, but some think apocryphally, as luminous insects.

FIRE, GREEK. This fire, which was employed in the wars of the Christians and Saracens in the middle ages, is said to have been invented during the reign of Constantine Pogonatus in the year 668 by Callinicus, an architect of Heliopolis. Naphtha was probably its principal ingredient, which, if skilfully projected and enflamed, creates great havoc and dismay, in consequence of its extreme combustibility and the difficulty of quenching its flame. (See a learned paper on this subject, by *Dr. M'Culloch*, in the *Quarterly Journal of Science*, vol. xiv.)

FI'RE-LOCK, or FUSIL. A musket or small gun, which is fired with a flint and steel; and thereby distinguished from the old musket, or *match-lock*, which was fired with a match. The date of the invention of firelocks is uncertain.

FIRE, ST. ANTHONY'S. *See* ERYSIPELAS.

FI'RE-WORKS. Artificial preparations made of gunpowder, sulphur, and other inflammable ingredients, displayed at public rejoicings and on other occasions. *See* PYROTECHNY.

FI'RKIN. A measure of capacity, being the fourth part of a barrel, or containing 9 ale gallons, or 7½ imperial gallons; that is, 2538 cubic inches.

FI'RLOT. A dry measure used in Scotland, but of different capacities, according to the article it is used for measuring. The Linlithgow *wheat firlot* is to the imperial bushel as ·998 to 1; and the *barley firlot* to the imperial bushel as 1·456 to 1.

FI'RMAMENT, in the language of the old astronomers, is the orb of the fixed stars, or the most remote of all the celestial spheres. In common language it signifies the same thing as *heaven*, or *sky*. *See* HEAVEN.

FI'RMAN (more properly *Fermân*), in the Persian language, signifies a command, and is the name given in Turkey, Persia, and India to mandates or certificates of the sovereign, issued for various purposes. Those best known to Europeans are given to travellers, and serve as passports. The Fermân has placed at its head in Turkey the cipher of the reigning sultan, written in a complicated manner, affixed by the chief secretary of the sign manual.

FIRST COAT. In Architecture, the *laying* the plaster on the laths, or the *rendering*, as it is called, on brick when only two coats are used. When three coats are used, it is called *pricking up* when upon laths, and *roughing in* when upon brick.

FIRST FRUITS. (Annates, or Primitiæ.) The profits of every spiritual living for the first year after its avoidance, which the new incumbent paid in Catholic times to the Pope, but since the Reformation to the king. The valuation is that which was made by Henry VIII. The stat. 2 Anne transfers the first fruits and tenths of all livings over 50*l*. at that time to a fund called Queen Anne's Bounty, for the increase of the smaller benefices, which are released from any payment of the kind.

FIRTH. *See* FRITH.

FISC. (Lat. fiscus.) The term used in the Roman law, and laws derived from it, to denote the property of the state. Under the emperors, however, it had acquired the signification of the peculiar domain or treasure of the prince, in contradistinction to *ærarium*, the public treasury. The word confiscation is derived from fisc; and every lord or body corporate to which things may be confiscated in course of law has, properly speaking, the right of fisc. Fiefs, being originally lands granted to individuals out of the king's domain, are sometimes termed *fisc* in writers of the middle ages. *See* FEUDAL SYSTEM.

FI'SCAL. Something relating to the pecuniary interest of the sovereign, or the community.

FISH. In Architecture, a piece of wood secured to another to strengthen it.

FISH. *See* PISCES.

FI'SHERY. The fisheries of the British Islands are partly coast and river, and partly carried on in the open sea at a greater or less distance from the shore. Of the former, salmon, herring, pilchard, and oyster are most important; of the latter, cod, turbot, and whale. 1. The salmon fishery has considerably diminished in importance of late years. That of Scotland is regulated by 9 G. 4. c. 39. and subsequent acts. 2. The herring fishery, at first almost engrossed by the Dutch, was fostered in 1749 by a tonnage bounty granted on vessels employed in it. Under this system the fishery does not appear to have thriven. The bounty was gradually withdrawn, and finally ceased in 1830. The most important seats of the herring fishery at the present day are the coasts of the north-east of Scotland. In 1834, 11,000 boats and 82,000 persons (fishermen and boys, coopers, curers, &c.) were employed in this fishery. 3. The pilchard fishery is a limited business, carried on almost entirely on the coasts of Devon and Cornwall. 4. Oysters are found on most parts of our coasts, but the principal seats of the trade of breeding them for the London market are Kent and Essex. 5. Turbot, cod, and mackerel are the principal articles of the fisheries off the British coasts. Turbot are chiefly caught by Dutch fishermen, and close to the shores of Holland. In 1833 a report was made by a committee on the British Channel Fisheries, in which the declining state of those fisheries is much commented upon, and attributed to three causes: the extensive interference and aggression of the French fishermen on the coasts of Kent and Sussex; the large quantities of foreign-caught fish illegally imported and sold; and the great decrease and comparative scarcity of fish in the channel; which last they attribute to the destruction of spawn. But by far the greatest fishery of cod, hake, ling, &c. is that carried on on the great bank of Newfoundland, and on the neighbouring coasts. The former is now chiefly engrossed by the French and Americans; but the British fishery, although principally confined to the coasts of Newfoundland and Labrador, is very extensive. Mr. M'Gregor, in his work on the North American Colonies, estimates the value of the produce, on an average of five years to 1832, at 857,000*l*. per annum. (ii. 596.) 6. The Greenland whale fishery was engaged in by the English in the 17th century, but not with vigour until encouraged by a bounty in 1740. During the late war it became extremely valuable; afterwards it declined in importance. In 1815, 146 vessels sailed; in 1834, 76 only. The southern whale fishery is a more modern branch of the traffic. (See *M'Culloch, Statist. of Great Britain*, ii. 21. &c.; article "Fisheries," in *Enc. Brit.*, new ed.; Report of the Committee on the Channel Fisheries, 1833: the former writer estimates the annual value of the fisheries at about 3,000,000*l*. per annum.) The coast and sea fisheries are protected by a variety of enactments. Fishing vessels are licensed by the commissioners of customs under 6 G. 4. c. 108. As to inland fishing, the law of offences in private fisheries is now consolidated by 7 & 8 G. 4. c. 27. Taking or destroying fish in water running through, or in land adjoining or belonging to the dwelling-house of the owner of the water, is a misdemeanour; in any water not within this description, but private property, or in which there is a private right of fishing, it is punishable with fine on summary conviction. Angling in the daytime is not within these enactments, but is punishable summarily with less penalty. The right of fishing in a river primâ facie belongs to the lord of the manor, who has the ownership of both banks. Fishery is said to be either several or free, or common of piscary. The first is in the owner of the soil, or one deriving title from him; the second is a royal franchise, conveying an exclusive right of fishing in a public river. Common of piscary is a liberty of fishery in common with others in a stream or river the soil whereof belongs to a third person, and resembles other commonable rights.

FISHPONDS, are ponds made by art, in which different kinds of fish are bred and fattened. In general this is only attempted with fresh-water fish; but in some places ponds have been formed on the sea shore, and so contrived as to have their waters renewed every tide, and in these sea fish have been kept for use for a considerable time. The fresh-water fish which is the most successfully managed in ponds is the carp.

FISSI'PARA. (Lat. findo, *I divide*, and pario, *I engender*.) Those animals are so called which propagate by spontaneous fission, or the detachment of a greater or less proportion of the body, having inherent power of self-support and growth. As the animals which manifest this mode of generation differ widely among themselves in their general organization, the term *fissipara* cannot be applied to designate any natural group; spontaneous fission is limited to the lowest classes of animals, as *Infusories*, *Polyps*; certain worms, as the *Naïs*, &c.

FISSIRO'STRALS, *Fissirostres*. (Lat. findo, and rostrum, *a beak*.) The name of a tribe of perching birds (*Insessores*), comprehending those which have a very wide gape, as the swallow.

FISSURE'LLA. (Lat. findo.) A genus of Gastropodous Mollusks, having a shell shaped like that of a limpet (*Patella*), but with a fissure at the apex of the cone, which opening is associated with a different form and arrangement of the breathing organs.

FI'STULA. (Lat. *a pipe*.) A long sinuous ulcer, often communicating with a larger cavity, and having a small external opening.

FI'STULA SPIRA'LIS. In Botany, a term used by Malpighi to denominate that kind of vegetable tissue now called the spiral vessel.

FISTULI'DANS, *Fistulides*. (Lat. fistula, *a pipe*.) A tribe of Echinodermatous animals, comprehending those which have an elongated cylindrical tube-like body.

FIVE POINTS. The principal points of controversy between the Calvinists and Arminians, which became the subjects of the decisions of the Synod of Dort. They relate to predestination, satisfaction, regeneration, grace, and final perseverance. See article ARMINIANS.

FIXED AIR. The old term for *carbonic acid*, from its existence in a fixed state in limestone, &c.

FIXED OILS. The common greasy oils are so termed in consequence of the high temperature which they sustain before giving out vapour.

FIXED STARS. Those which retain the same, or very nearly the same position, with respect to each other. It has been discovered, by the acccurate observations of modern times, that many of the stars have a proper motion. *See* STARS.

FI'XTURE, in Law, is a term generally applied to all articles of a personal nature affixed to land. This annexation must be by the article being let into or united with the land, or with some substance previously connected therewith. Thus a barn, built on a frame not let into the earth, is not a fixture; a brewer's stills, set in brickwork resting on a foundation, are fixtures; and the application of the same principle gives, in every case, the true rule to judge whether any thing be a fixture or not. Whatever is thus fixed becomes, by law, parcel of the freehold or realty. It is, therefore, on general principles, not removable; but there are exceptions to this rule established by custom; of which the principal arise out of the right of tenants to remove fixtures set up for purposes of trade, and in some instances for ornament and convenience (commonly called tenants' fixtures), and the right of executors to some fixtures, generally of the same description, as against the heir or devisee of the realty.

FLAG. In Naval affairs, the flags are,— the royal standard; the admiralty flag, an anchor on a red ground; the union, or jack, in which are blended together the crosses of St. George, St. Andrew, and St. Patrick: this is carried by the admiral of the fleet.

FLAGE'LLA. A term used by the older botanists to denote the twigs or youngest shoots of plants.

FLAGE'LLANTS. (Lat. flagellum, *a whip.*) A sect of enthusiasts who first appeared in the middle of the 13th century, and being then repressed, sprang up again with renewed violence in the 14th. Beginning first at Cremona in Italy, the contagion of the example spread in a few years throughout Europe; and every city was infested by multitudes who went naked from the loins upward, and inflicted upon themselves several daily flagellations, with the idea of obtaining thereby merit in the eyes of God. They formed themselves into a society, and at first were at least innocent in their behaviour; but as their numbers increased, they gave way to great excesses, and were eventually suppressed by a holy war proclaimed against them by Pope Clement VI.

FLAGE'LLUM. In Botany, a trailing shoot of the vine; sometimes used to denominate that form of stem called a runner.

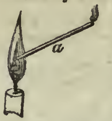
FLA'GEOLET. (Fr.) A wooden musical wind instrument, played with a mouth-piece, the holes and keys whereof are stopped with the fingers, in the same way as the flute.

FLAIL. A wooden implement for threshing corn by hand. It consists of the handle or hand-staff, which the labourer holds in his hand, and uses as a lever to raise up and bring down the swiple, or part which strikes the corn, and beats out the grain and chaff from the straw. The swiple is joined to the hand-staff by the caplins or couplings, which are thongs of untanned leather, and sometimes the skins of eels or of other fish. These thongs are passed through holes in the ends of the handle and swiple, and made fast by being sewed together. The flail was in use among the Romans, though the prevailing mode of separating corn from straw among the nations of antiquity was by treading it out with cattle in the open air. In the colder parts of Europe, this could never have been generally the case for obvious reasons; and hence the flail was the universal threshing implement till the introduction of the threshing machine, which is now taking the place of the flail in all countries where capitalists engage in farming. *See* THRESHING MACHINE.

FLAKE WHITE. A term often applied to the purest *white lead.*

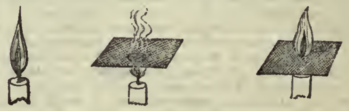
FLAME. (Germ. flamme.) When the temperature of inflammable gases or vapours is raised very high, and in the contact of air, they are said to *burst into flame;* if previously mixed with a due proportion of oxygen, or of atmospheric air, they *explode.* In the former case the combustion only goes on at the surface in contact with air, and is quiet and gradual; in the latter, every particle of the inflammable body being in contact with the supporter of combustion, the inflammation extends instantaneously through the whole mass. The nature of flame was first explained by Hooke in 1677 (in his *Lampas*); but the relation of the light to the heat of flames, and the whole philosophy of their constitution, was first developed by Sir H. Davy in his researches published in the *Philosophical Transactions* between 1815 and 1817.

All the leading phenomena of flame are well exhibited by a large gas-flame burning from a wide orifice. It presents a hollow cone, the heat and light of which are confined to its exterior surface. A transverse section of such a flame exhibits a ring of light surrounding a central uninflamed core: the inflammable gas or vapour may be drawn by a tube out of this central portion, as in the annexed figure, where *a* represents the tube inserted into the central non-luminous part of the flame, and where the abstracted inflammable vapour is again kindled at its extremity. (See illustrations of this subject in the papers of Mr. Sym and Mr. Davies, *Ann. of Phil.* vols. viii. and x.)



A flame may be extremely hot without being proportionately luminous, as is the case with the flame of hydrogen, which is scarcely visible in daylight, but the heat of which is shown by introducing into it a piece of fine platinum wire, which immediately becomes white hot, and emits abundance of light. The *light* of all flames is of a similar origin, and depends upon *solid matter* ignited and rendered incandescent by the heat of the flame: thus if magnesia or lime in fine powder be projected into the flame of hydrogen, the luminosity of the flame is immediately increased. Finely divided charcoal is the substance to which all common flames owe their luminosity. It is derived from the hydrocarbon produced by the decomposition of oil, wax, tallow, &c., as contained in coal gas; but as charcoal, unlike magnesia and lime, is itself combustible, it not only renders the flame luminous, but is burned in the act of so doing, and passes off in a well-regulated and perfect flame in the invisible form of carbonic acid gas.

When flames are cooled, they are at the same time extinguished; hence a flame cannot be made to traverse or recede through a metallic tube of small bore; and hence a flame may, as it were, be bisected by a piece of wire gauze held transversely across it: in which case the smoke, gas, or vapour and charcoal go through, but not hot enough to inflame, having been cooled down by their passage through the metallic meshes; but by applying a flame to this smoke, it may again be kindled. In this way the upper portion of the flame may be burned, while the inflammation of the lower half is prevented by the interposed cooling medium. These experiments are best illustrated by the flame of a gas-burner, and the two cases just cited are represented in the annexed figures.



FLA'MEN. The title applied by the Romans to the priests of any particular deity as distinguished from priests in general. Originally Numa instituted three orders of flamens; viz. those of Jupiter, Mars, and Quirinus (Romulus). But in after times this number was much increased by the introduction of new gods and superstitions, and by the worship paid to deceased emperors.

FLAMI'NGO. *See* PHŒNICOPTERUS.

FLANK. (Fr. flanc.) In Architecture, the side of any building.

FLANK, in Fortification, is that part of the bastion which reaches from the curtain to the face: the flank of one bastion serves to defend the ditch before the curtain and face of the opposite bastion. *See* FORTIFICATION.

FLANNEL. *See* WOOLLEN MANUFACTURE.

FLA'SHINGS. (Probably from flaque, *a splash.*) In Architecture, pieces of lead or other metal let into the joints of a wall so as to lap over the gutters or other conduit pieces, and prevent the splashing of rain injuring the interior works.

FLAT. In Architecture, that part in the covering of a house of lead or other metal which is laid horizontal.

FLAT. In Music, a character of this form ♭, which depresses the note before which it is placed a chromatic semitone. Flats and sharps were originally contrived to remedy the defects of musical instruments whereon temperament was required, the natural scale of music being limited to certain fixed sounds, and adjusted to an instrument in many points defective; for we can only proceed from one note to another by a particular order of degrees. Hence, from one note to another, upwards or downwards, we cannot find any interval at pleasure. To supply or remedy this defect, musicians have had recourse to a scale proceeding by twelve degrees, making therefore thirteen notes to an octave, including the extremes, which, though it does not make the instrument perfect, leaves little room for complaint. In instruments whose sounds are fixed, a sound or note dividing it into two unequal parts, called semitones, is placed between the extremes of every tone of the natural scale; so that we have twelve semitones between thirteen notes in the compass of an octave. In order then to keep the diatonic series distinct, the inverted notes answer for the name of the natural note next below, with this character ♯, called a sharp; or the name of the natural note next above it, with this character ♭, called a

flat. Thus D♭ signifies a semitone below D natural (♮). On keyed instruments the short keys are the representatives of these flats and sharps. The system, however, does not strictly produce what it represents: it is only an approximation. *See* TEMPERAMENT.

FLAT FIFTH. In Music, an interval of a fifth depressed by a flat, called by the ancients *semidiapente*.

FLAT FISH. *See* PLEURONECTES.

FLA'TTEN A SAIL. To extend it fore and aft, whereby its effect is lateral only.

FLATTING. In Architecture, a coat of paint, which, from its mixture with turpentine, leaves the work flat, or without gloss.

FLA'TULENCY. (Lat. flatus, *blast.*) A morbid collection of gas in the stomach and bowels, commonly symptomatic of indigestion or indulgence in certain kinds of vegetable food. Warm tonics and well-seasoned animal food, with weak brandy and water as a beverage at dinner, are the usual and effective remedies.

FLAX. (Germ. flachs.) The fibre of the *Linum usitatissimum*, which is spun into thread and woven into *linen* textures.

The flax is reaped a little before the seeds are ripe; it is stripped, and the stalks are then soaked in water, or *retted* (rotted), when fermentation running into putrefaction ensues, so as to destroy the foreign matters with which the fibres are blended in the plant; the flax is then dried, and broken or beaten and winnowed, so as to separate the fibrous from the other parts; these are afterwards heckled, and prepared for the spinner. (For an account of these operations, and of the machinery by which they are effected, see Ure's *Dictionary of Arts, &c.*, art. "Flax.")

FLECHE. In Fortification, a simple redan usually constructed at the foot of a glacis. *See* REDAN.

FLEECE, ORDER OF THE GOLDEN. One of the most distinguished among European orders of knighthood. It was founded by Philip III., duke of Burgundy, in 1430; and as by its foundation his successors were declared to be hereditary grand masters, that title passed, with the Burgundian inheritance, to the house of Austria; thence, after the death of Charles V., to the Spanish line of that house: but when the monarchy of Spain passed to the Bourbons and the Spanish Netherlands to Austria, the archdukes of Austria claimed the grand mastership; and claims are made on it at present both by the emperor of Austria and king of Spain; the order is consequently conferred both at Vienna and Madrid, and is, in both courts, the highest in point of rank. As its nominal object is the protection of religion, it is rarely conferred on any Protestants, with the exception, by courtesy, of Protestant sovereigns.

FLEET, in its most extended signification, is applied to a number of ships, pursuing in company either mercantile or warlike purposes, or both; but is more generally confined to the different detachments which form the *navy* of any country, stationed in various parts of the world for the purposes of defence, aggression, or intimidation. *See* NAVY, SQUADRON.

FLEET. The sea term for shortening any thing, by taking it up, that had been pulled out or stretched.

FLE'MISH SCHOOL. In Painting, the school formed in Flanders. The works of this school are distinguished by the most perfect knowledge of chiaro-scuro; high finishing without dryness; by an admirable union of colours well blended and contrasted, and by a flowing luxurious pencil. Its defects are somewhat similar to those of the Dutch school. The Flemish painters, like the Dutch, represented nature as they found her, and not as she should be. Rubens and Vandyke (the glory of this school), though men of the greatest genius, were not free from this defect, and the former especially. Teniers was another great master of the school in question; to it also belong Snyders, Steenwick, Neefs, Schwaneveldt, Van Eyck, &c.

FLE'TA. The title of an ancient treatise on English law, attributed to the reign of Ed. I., and named (according to tradition) from its composition by a judge in the Fleet prison.

FLEUR-DE-LIS. In Heraldry, a charge supposed to represent a lily: borne from a very early period in the royal arms of France. It is, however, more probably conjectured that the shape of this bearing was intended to represent the iron of a javelin.

FLE'XIBI'LITY. (Lat. flecto, *I bend.*) That property of bodies in virtue of which, when a sufficient force is applied to them, they change their form, and are bent. Flexibility is opposed to *stiffness* on the one hand, and to *brittleness* on the other; stiff bodies being such as resist bending, and brittle those which cannot be bent without a disruption of their parts. Of unorganized bodies the most flexible are the metals; and their flexibility is in general increased by heat, though brass is rendered brittle when subjected to a high temperature. Of organized bodies, young fresh plants and animal substances (excepting bone) are eminently flexible; and bodies of this class are rendered more flexible by heat and moisture. In many machines where great stability is required it is often a matter of much importance to be acquainted with the flexibility of the component materials, in order to determine the load they can support without yielding. (*See* COHESION.) Flexibility is only a relative term, for all bodies are more or less flexible; and in bars of wood or metal the stiffness or resistance to flexure is directly as the breadth and cube of the depth, and inversely as the cube of the length.

FLEXU'RA. (Lat. flecto, *I bend.*) In Mammalogy, the joint between the antibrachium and carpus, usually called the fore-knee in the horse; analogous to the wrist-joint in man.

FLE'XURE. The bending or incurvation of a line or surface. *Point of contrary flexure* is a term used in analytical geometry to denote that point of a curve at which the curvature passes from convex to concave, or *vice versâ*, with respect of the axis. At this point the radius of curvature is infinite. At the points of the curve immediately preceding and following, the centre of curvature lies on opposite sides of the curve.

FLINT. Common flints are nearly pure *silica*. They usually occur in irregular nodules in chalk. Their origin is an unsolved geological problem.

FLINT GLASS, or CRYSTAL. A species of glass which derives its name from flint, because that substance was formerly employed in its manufacture. It is very extensively used for domestic purposes; but is chiefly interesting to the philosopher on account of the property which it possesses of causing a greater dispersion of the rays of light which pass through a prism or lens formed of it than any other of the vitreous compounds. This property renders it invaluable in the manufacture of the object glasses of telescopes and microscopes; for by combining a concave lens of flint glass with one or two convex lenses of *crown glass*, which possesses a much less dispersive power, a compound lens is formed, in which the prismatic colours arising from a simple refraction are destroyed, and the lens rendered achromatic. This construction of object glasses was first discovered by a Mr. Hall, a country gentleman in Worcestershire, about 1729; but the discovery was forgotten, and no further notice taken of it for nearly 30 years, when it was again brought to light by John Dollond, after a long-continued course of experiments undertaken for the purpose of perfecting the telescope. It is, however, very difficult to prepare flint glass fit for the purposes of achromatic telescopes. This difficulty arises not from the want of sufficient dispersive power in the substance, but from the want of purity or homogeneity; the slightest impurity or inequality of composition in the glass giving rise to a streaked or imperfect image by reason of the unequal refraction of the rays. The composition of pure flint glass long remained a secret in the family of the Dollonds, and its manufacture formed a very profitable article of exportation; for till about the beginning of the present century, no flint glass of good quality was made on the Continent. Of late years, however, a great change has taken place in this respect; and glass of the best quality has been manufactured, both in France and Germany, in much larger masses than our English artists have yet succeeded in obtaining. This result has been mainly produced by the experimental researches of D'Artigues, Fraunhofer, Cauchoix, Guinand, and Korner. Formerly, an object-glass exceeding five inches in diameter could scarcely be produced. Fraunhofer succeeded in making them of nine, and even twelve inches. The object-glass of the large parallactic telescope belonging to Sir James South, at Campden Hill, was manufactured by Cauchoix; it exceeds twelve inches, and is throughout of the utmost purity. The exact proportion of the ingredients which enter into these choice specimens is not known, and probably their excellence depends in part on some accidental circumstances in the preparation. Korner produced some of his best specimens by employing the following ingredients: — 100 parts of quartz, first treated with muriatic acid; 80 parts of litharge, or red lead; and 30 parts of the bitartrate of potash. Flint glass for common purposes is usually made of 120 parts of fine white sand, 40 parts of well purified pearl ash, 35 parts litharge or minium, 13 parts nitre, and a small quantity of the black oxide of manganese; the latter ingredient being used to correct the green colour occasioned by the presence of oxide of iron in the sand. The principal difference between this and the glass used for optical purposes consists in the much greater quantity of lead in the latter, and which is introduced for the purpose of increasing its dispersive power. There is a valuable paper on the manufacture of glass for optical purposes, containing the results of an extensive series of experiments upon the subject, made in the laboratory of the Royal Institution, by Mr. Faraday, in the *Philosophical Transactions* for the year 1830, vol. cxx. *See* GLASS.

FLOAT BOARDS. The boards fixed to the rim or outer circumference of undershot wheels, which receive the impulse of the water and communicate the motion to the wheel.

FLOA'TED LATH AND PLAISTER. In Architecture, plaistering of three coats, whereof the first is pricking up (*see* First Coat); the second, floating or floated work; and the last of *fine stuff.*

FLOA'TED WORK. In Architecture, plaistering made of a perfectly plane surface, by means of a tool (which is a long rule with a straight edge) called a float.

FLOA'TING MEADOWS. Meadow lands, the surface of which is flat, adjoining a river or other source of water, with which they can be flooded or covered at pleasure. The water is turned on chiefly in the winter season, when it is more or less muddy, and leaves a deposit that serves as a kind of manure. It is also useful to vegetation, by preserving a higher temperature in the surface soil than it could maintain through the winter, if fully exposed to the action of the atmosphere; because, wherever water is in a fluid state, its mean temperature, and that of the bodies immediately in contact with it, must be above 32°, and at that temperature the grasses common in British meadows will grow. There are probably other benefits which grass lands receive from being covered with water during a portion of the winter season, but these have not yet been satisfactorily explained by science.

FLOA'TING SCREEDS. (Ital., probably from schierato, *ranged.*) In Architecture, strips of plaister arranged and nicely adjusted for guiding the *floating-rule.* *See* Floated Work.

FLOA'TSTONE. A porous variety of flint, which floats upon water.

FLO'CCI. (Lat.) In Botany, the woolly filaments that are found mixed with the sporules of many *Gastromyci:* the same name is also applied to the external filaments of *Byssaceæ.*

FLOCCILLA'TION. Picking the bed-clothes. This is a very alarming symptom in many acute diseases.

FLO'CCUS. In Mammalogy, the tuft of long flaccid hairs which terminate the tail.

FLOETZ ROCKS. A term applied by the German geologists to the secondary strata, because they generally occur in *flat* or horizontal beds.

FLOOR. (Sax. flope.) In Architecture, the pavement or boarded lower horizontal surface of an apartment. It is constructed of earth, brick, stone, wood, or other materials. Carpenters include in the term the framed timber work on which the boarding is laid, as well as the boards themselves.

Floor. The lower part of a ship's bottom.

FLOOR CLOTH. This useful and ornamental manufacture originated in this country about the year 1740, when a manufactory of it was established at Knightsbridge, near London, by Mr. Smith. It was originally made of narrow canvass sewn together like sail cloth, to which successive coats of paint were applied; but the seams proving inconvenient, a canvass was wove for the purpose, about four yards wide; it was then extended to seven yards in width, and afterwards to nine, which is the widest at present made. The manufactory at Knightsbridge, now carried on by Mr. Baber, is the largest establishment of the kind; the common dimensions of the oil cloths produced there being 20 yards by 8, and 30 yards by 7, giving therefore entire pieces of 160 and 210 square yards without seams. These canvasses are stretched upon frames, and accessible over their whole surface by stages erected for the purpose: these are the circumstances which render the large dimensions of the manufactory requisite. The canvass being duly strained is rubbed over with pumice stone, which renders its surface smooth and even, and then brushed over with a weak solution of size; when this is dry the first coat of oil colour is laid on, not with brushes, but with trowels, something in the manner of plastering; when this is dry a second coat follows it; and in this way seven coats of paint are usually applied in succession, three on the back and four on the front. When the cloth in this state, and of one colour, is sufficiently dry, it is removed from its frame upon a large roller, and carried to the upper part of the building to be *printed;* that is, to receive its pattern. This was originally effected by a process of stencilling; but in the year 1780 Mr. Smith introduced the great improvement of *block-printing,* by which the colours are more correctly laid on, and in greater body and variety. The printing table, which is about 30 feet long, 4 wide, and 2 feet 6 inches high, is very firmly constructed of deal timbers laid edgeways and clamped together, the surface being truely planed; the roll of painted cloth is placed underneath it, and as it is unrolled it gradually passes over the table, where it is printed, and is then drawn forward so as to hang perfectly free while drying, the height of the building being such as conveniently to admit of this, without rolling, doubling, or folding the material, which in these stages would of course injure it. The colours, which are the usual oil colours very carefully prepared, are put on in succession with wooden blocks, which are made of pear tree, box, or holly wood, and upon which the patterns are cut in relief; they are about eighteen inches square, and are applied in succession over the whole of the surface of the cloth lying upon the printing table. Every colour is put on by a separate block, and much dexterity is required in so placing them that the patterns may correctly interlace and join each other, without in any case overlapping or interfering: to effect this the workman is aided by guide pins, or *pitches,* as they are termed, which direct him in placing the block. The colours are first brushed or tiered upon hard cushions, from which they are transferred to the block, and thence to the cloth; and, though many are often required, it is astonishing how much effect is sometimes obtained by the judicious arrangement or mixture of two only, upon a third, which forms the ground. It will be obvious, from what has been stated, that the weight of the finished oil cloth, as compared with the naked canvass, is no unimportant criterion of its goodness; each square yard when finished weighing from three pounds and a half to four or four and a half: this distinguishes a good oil cloth from those which are vamped up and stiffened with size and other perishable materials.

Independent of the common application of oil cloth, it is not unfrequently advantageously employed as a roofing material, especially for covering verandas and other light structures. When used for this purpose, the canvass should be made of picked long flax, and thoroughly saturated with good oil paint; it will then stand our climate and last for 14 or 15 years.

FLOOR, FOLDING or FOLDED. In Architecture, one in which the floor boards are so laid that their joints do not appear continuous throughout the whole length of the floor, but in bays or folds of three, four, five, or more boards each.

FLOOR, STRAIGHT JOINT. In Architecture, one in which the floor boards are so laid that their joints or edges form a continued line throughout the direction of their length; in opposition to folding floor, where the joints end in folds.

FLORA'LIA. A festival celebrated with some magnificence in honour of Flora, the Roman goddess of flowers.

FLO'RETS. The flowers of a capitulum or anthodium; which are smaller in size, but not different in structure from ordinary flowers. Those which are placed in the middle of the capitulum are called *discoidal,* or *of the disk;* those in the circumference are named *radiant,* or *of the ray.*

FLORIN. *See* Money.

FLOS-FERRI. A coralloidal carbonate of lime, often found in veins of spathose *iron* ore.

FLOTA. A name given by the Spaniards to the ships that formerly sailed together, or under convoy, from Cadiz and the other ports of the Peninsula authorized to trade directly with the Transatlantic possessions of Spain.

FLOTI'LLA. (Span.) Literally a little fleet; in which sense, however, it is seldom used, being applied almost invariably to a fleet, how large soever, composed of small vessels. Thus the term flotilla was given to the immense naval force with which Napoleon meditated the invasion of Great Britain, and which consisted of 2365 vessels of every description, was manned by about 17,000 sailors, and carried 160,000 soldiers, and 10,000 horses. In Spain, the name flotilla is given to a number of vessels appointed to announce to the home government the departure and nature of the cargo of the flota or mercantile ships from foreign ports on their homeward voyage.

FLO'TSAM (floating), *Jetsam* (Fr. jeter, *to throw*), and *Lagan* (lying), as law terms, are usually joined together. The first, according to Blackstone, designates goods cast from a ship and swimming in the waves; jetsam, goods cast and sunk; lagan, sunk but tied to a buoy by the owners. Goods in either of these three predicaments belong to the king, if the owners be not known, and may by him be granted with other franchises.

FLOW'ERLESS PLANTS. Those plants that are destitute of flowers and sexes. They are the same as *cryptogamic,* or *acrogenous,* or cellular plants.

FLOWERS. The old chemists gave this name to several light flocculent substances obtained by sublimation; such as *flowers of sulphur, flowers of benzoes,* &c.

FLUE. In Architecture, the long open tube of a chimney from the fireplace to the top of the shaft for voidance of the smoke.

FLU'ENT or FLOWING QUANTITY, in Analysis, is the variable quantity, considered as increasing or diminishing. The term denotes the same thing as *integral,* which is now universally used in its stead, the differential and integral calculus having superseded the methods of fluxions and fluents. *See* Fluxion, Integral.

FLU'ID, or FLUID BODY, is that whose parts yield to the smallest pressure, and are moved among each other without any sensible resistance. Some writers distinguish between *fluid* and *liquid,* confining the latter term to those substances which *wet,* or whose particles adhere to other bodies plunged into them. Thus air, ether, mercury, water, alcohol, &c. are all fluids; but water and alcohol are also *liquids,* because they wet other

bodies, while air and mercury do not. The term liquid is, however, very frequently used in the same general sense as fluid. Fluids are of two kinds, elastic and non-elastic. The mechanical properties of elastic fluids, comprehending air and the different gases, constitute the science of *Pneumatics;* those of the non-elastic fluids, water, mercury, &c., *Hydrostatics* and *Hydraulics*. It is to be remarked, however, that the terms elastic and non-elastic are here used in a relative, not in an absolute sense; for water, alcohol, and probably all other fluids of the same class, are, to a certain extent, compressible and elastic, though they resist compression with a very great force.

FLUI′DITY (Lat. fluo, *I flow*), is that state of a substance in which its constituent particles are so slightly cohesive that they yield to the smallest impressions. The term is usually confined to express the condition of the non-elastic fluids; and hence it denotes one of the three states in which matter exists; namely, the solid, the fluid or liquid, and the gaseous. The state of fluidity is best defined as that in which bodies tend to form *drops*, as this disposition does not belong either to bodies in a gaseous form, or to solid bodies reduced to fine powder. The formation of drops arises from this—that the molecules of fluid bodies adhere to each other with a certain force, at the same time that they glide over one another without any sensible resistance. It is incorrect to say that the molecules of bodies in a state of fluidity offer no resistance to separation; for, on bringing a flat disc of glass or metal into contact with the surface of a liquid, a very sensible degree of force is required to separate them. That adhesion exists among the molecules of fluid bodies is also proved by various other phenomena. Water or mercury on a flat plate of metal collects in globules, and when slowly poured into a wine glass will remain heaped up as it were above the level of the edge.

Various hypotheses have been framed by philosophers to explain the different states in which matter is found to exist. Confining ourselves to the most general views, we may regard all bodies as assemblages of particles constantly maintained in equilibrium between two forces,—an attractive force which tends to unite the particles, and a repulsive force which tends to increase the distance between them. The solid state results from the preponderance of the attractive force. Conceive the repulsive force to receive an augmentation until it becomes equal to, or forms an equilibrium with, the attractive force. When the two forces are thus balanced, the particles exert on each other neither attraction nor repulsion, and the body is in the fluid state. Lastly, if the repulsive energy be still increased, the particles will be separated from each other to such distances that their mutual attractions will cease altogether to be sensible, and then the body passes into the gaseous state. Hence we may pronounce that there is no *natural* state of body; and that fluidity, solidity, the state of vapour, and the aëriform state are only accidental, and determined by the temperature of the medium in which the body is placed. *See* CRYSTALLIZATION, CAPILLARY ATTRACTION, GAS, &c.

FLUKE. A name commonly applied to a species of flat fish, or *Pleuronectes;* and also to an *Entozoon* of a similar form (*Distoma hepaticum*), which infests the ducts of the liver of different animals, especially of the sheep.

Fluke is also applied in navigation to the broad part of the anchor which takes hold of the ground.

FLUOBO′RIC ACID. A gas obtained by heating to redness a mixture of dry boracic acid and powdered fluor spar. Its specific gravity is 2·36. It is colourless, pungent, and produces a dense white cloud when it escapes into a moist atmosphere; it is resolved by the action of water into boracic and hydro-fluoric acids. It acts with great energy upon animal and vegetable substances, and chars them. It is probably a compound of 20 parts of boron and 108 of fluorine; or of one atom of boron and six atoms of fluorine.

FLUO′RIC ACID. *See* HYDROFLUORIC ACID.

FLU′ORINE. The hypothetical base of the hydrofluoric acid: it has not yet been obtained in a separate state.

FLU′OR SPAR. This is a common mineral product, found in great beauty in Derbyshire; hence known in this country under the name of the *Derbyshire spar*. It is generally crystallized in cubes, but its primitive form is an octahedron. It is of various colours, and often beautifully banded; especially when in nodules, which are much prized for the manufacture of vases, and occasionally used for beads, brooch stones, and other ornamental purposes. It is probably a compound of fluorine and calcium, hence a *fluoride of calcium*. The term *fluor* is derived from the fusibility of this substance; on which account it is sometimes used as a flux to promote the fusion of certain refractory minerals. It is manufactured at Matlock and Derby into a great variety of articles.

FLU′OSI′LICIC ACID. A gas obtained by applying a gentle heat to a mixture of one part of powdered fluor spar, one of silica, and two of sulphuric acid, in a retort. It is colourless, pungent, fumes when it escapes into a humid air, and is rapidly absorbed by water. Its specific gravity is about 3·6; 100 cubic inches weighing nearly 112 grains. It is decomposed by water, and forms silica and hydrofluoric acid. It consists of 8 parts by weight of silicium, and 18 of fluorine, its equivalent (upon the hydrogen scale) being 26.

FLUSH. (Lat. fluxus.) In Architecture, the continued surface in the same plane of two contiguous masses.

FLUTE. (Fr.) A wooden musical wind instrument played by holes and keys, stopped and opened with the fingers. The lips and tongue are both used in playing it. The octave flute is a smaller but similar instrument, whose pitch is an octave higher than the flute, as its name implies.

FLUTES, or FLUTINGS. (Fr.) In Architecture, upright channels on the shafts of columns, usually ending hemispherically at top and bottom. Their plan or horizontal section is sometimes circular or segmental, and sometimes, as in the Grecian examples, elliptical. The Doric column has twenty round its circumference; the Ionic, Corinthian, and Composite twenty-four. The Tuscan column is never fluted. They are occasionally *cabled*. (See that word.)

FLUVIA′LES. (Lat. fluvius, *a river*.) A natural order of Endogenous water plants common in all extra-tropical countries, and approaching somewhat to flowerless plants. Pollini, according to De Candolle, asserts that spiral vessels do exist in them, while Amici urges the contrary. Agardh refers to this order both *Ceratophyllum* and *Sparganium;* but those genera are nearer allied to *Juncaginaceæ*. Their sensible properties are unimportant. *Zostera* or sea wrack, one of the genera, is used to stuff cushions, and as a material for packing.

FLUX. (Lat. fluo, *I flow*.) Applied in technical chemistry to substances which are in themselves very fusible, or which promote the fusion of other bodies. When tartar is deflagrated with half its weight of nitre, a mixture of charcoal and carbonate of potash remains, which is often called *black flux:* when an equal weight of nitre is used, the whole of the charcoal is burned off, and carbonate of potassa remains, which, when thus procured, is called *white flux*. For flux and reflux of the sea, *see* TIDES.

FLUX. In Pathology, a disease attended by inordinate secretion from the bowels.

FLU′XION (Lat. fluxus, *flow*), in Analysis, signifies the same thing as differential, the term being suggested by a particular view of the manner in which variable quantities increase or diminish. Newton considered a curve as generated by the uniform motion of a point, and decomposed at every instant the constant velocity of this point into two others, one parallel to the axis of the abscissa, and the other parallel to the axis of the ordinates. These velocities are what he called the *fluxions* of the co-ordinates; while the arbitrary velocity of the point which describes the curve is the fluxion of the arc. Reciprocally, the arc described is called the *fluent* of the velocity with which it is described by the moving point; the corresponding absciss is the fluent of the velocity estimated in the direction of the absciss, and the ordinate the fluent of the velocity of the point estimated in the direction of the ordinate. The same considerations may be extended to the areas bounded by curve lines, to surfaces and the volumes which they determine, to forces which give rise to motion in bodies, and to the effects which they produce. In fact, the theory is applicable to every thing which forms the object of the mathematical or physico-mathematical sciences.

The method of fluxions is derived naturally from that of *prime* and *ultimate ratios;* for the variable velocity of a point is not the path described by it in a given time divided by this time; but it is the prime or ultimate ratio of that quotient, that is to say, the quantity to which that quotient approaches more and more in proportion as the time is supposed to be shorter. This observation has occasioned an objection to the method of fluxions,—namely, that of introducing into geometry, which is a branch of the pure mathematics, the idea of velocity, which belongs to the mixed mathematics; and of defining an idea which ought to be simple by one that is complex. The objection is frivolous; the only question of any consequence being whether the theory is more easily apprehended by this manner of exposition than by any other.

In applying the method of fluxions to mathematical investigation, the procedure is precisely the same as in the differential calculus; from which, indeed, it differs in no respect save that of notation. The method was invented by Newton; and the notation which he used was adopted by all English writers, and long obstinately adhered to, although the notation of Leibnitz, the inventor of the differential calculus, possesses over it many advantages, particularly in the more abstruse theories of analysis. At length, however, the great number of excellent works which appeared on the Continent, in all of which the differential notation was used, the manifest advantage of uniformity in the symbols employed in sci-

entific researches, and the intrinsic superiority of the foreign notation, caused that of fluxions to be gradually abandoned, and at the present time it has entirely disappeared in all mathematical works possessing any claim to merit. The first systematic treatise on fluxions in our language, in which the differential notation was employed throughout, was the article "Fluxions" in the *Edinburgh Encyclopedia*, which appeared in the year 1815.

FLY. In Mechanics, an appendage given to machines for the purpose of regulating and equalizing the motion, as in the windlass, jack, pile-engine, &c.; and sometimes for collecting force in order to produce a very great instantaneous impression, as in a coining press. Generally it is formed of a heavy disc or hoop at right angles to the axis; sometimes of heavy knobs at the extremities of a bar having the same position. The fly is of great use in all cases where the power, or the resistance, acts unequally in the different parts of a revolution.

FLY-CATCHER. *See* MUSCICAPA.

FLY'ING BUTTRESS. In Gothic Architecture, a buttress in the form of an arch, springing from a solid mass of masonry, and abutting against the springing of another arch which rises from the upper points of abutment of the first. It is seen in most of our cathedrals, and its office is to act as a counterpoise against the vaulting of the nave. If flying buttresses were built solid from the ground, it is obvious that they would interfere with the vista along the aisles of the church; hence the project of continuing a resistance by means of arches. Their stability depends on the resistance afforded by the weight of the vertical buttress from whence they spring. See the diagram, art. GOTHIC ARCHITECTURE AFTER THE 12TH CENTURY.

FLY'ING FISH. The species of two distinct genera of fish, in which the pectoral fins are so developed as to enable them to sustain themselves for a short time in the air, are so called. The more common species are the Exocœte (*Exocœtus volitans*), and the flying gurnard (*Dactylcptera volitans*).

FLY POWDER. An imperfect oxide of arsenic, formed by the exposure of native arsenic to the air; when mixed with sugar and water it is used to kill flies.

FO. The name given by the Chinese to Buddha, by one of those phenomena in literature whereby appellations are introduced from one language into others with which it has little or no affinity. Originally the name Buddha was expressed in the Chinese language with sufficient exactness by the term Fô-thau, pronounced Fôudah; but, as is usual in China with proper names, the last syllable was subsequently dropped. According to the Chinese historians, the religion of Buddha was introduced into China in the reign of Ming-ti, of the dynasty of the Hans, about the 64th year of the Christian era; but there is good reason to believe that the doctrines of the Indian reformer had been carried thither by some of his enthusiastic adherents long before that period, and that it is only to their official recognition by the government that this later date refers. This is not the place to give an exposition of the religious and philosophic principles of Fo (*see* BUDDHISM): suffice it to say that the same principles are adopted by all the Buddhists of the various countries where they are professed, with the exception of a few trifling deviations which the various translations of the Buddhist writings from their original Sanscrit have naturally generated. It is only when these writings, or at all events the chief of them, shall have been translated into the languages of Europe (which we have good grounds to suppose will soon be the case), that an accurate idea can be formed of the doctrines which they inculcate, and which have exercised so mighty an influence on the largest portion of the inhabitants of Asia. (See the *Penny Cyclopædia*.)

FO'CAL DISTANCE. (Lat. focus, *a hearth*.) In Optics, the distance between the centre of a lens or mirror, and the point into which the rays are collected.

FO'CUS, in Geometry, is applied to certain points belonging to the conic sections, which possess very remarkable properties. The focus of the parabola is a point in the axis having this property, that a radius drawn from it to any point in the curve makes the same angle with the tangent at that point that the tangent makes with the axis. Hence a ray of light proceeding from the focus, and reflected by the curve, proceeds in a direction parallel to the axis; or, if parallel rays fall on the concave side of a parabola, they are reflected into the focus. In the ellipse the two foci are situated in the greater axis, at equal distances from the centre; and if from both foci straight lines be drawn to the same point in the circumference, the two lines make equal angles with the tangent at that point. A ray of light, therefore, issuing from the one focus, is reflected by the curve into the other focus. In the hyperbola a similar property holds good; with this difference, that whereas in the ellipse the two straight lines fall both on the concave side of the arc, in the hyperbola one falls on the concave and the other on the convex; in other words, the two lines drawn from the foci to any point in the hyperbola make equal angles with the tangent on opposite sides of it. A ray of light, therefore, proceeding from one focus of a hyperbola, will be reflected by any point of the curve into the direction of a ray coming from the other focus and passing through that point. In the solar system, the sun occupies one of the foci of the orbits of all the planets and comets.

Focus, in Optics, is the space into which the rays of light are collected by a burning glass or mirror. On account of the apparent diameter of the sun's disc, the solar rays cannot be collected into a single point, even if we could suppose a lens or mirror to be formed into the perfect shape which geometry requires for that purpose. They cover a certain circular space, which space is called the focus; and its magnitude has the same relation to the apparent diameter of the sun, as the image of any other object formed in the focus of the lens or mirror has to the object itself. Let A C be a ray proceeding from the centre of the sun's disc, and B C another proceeding from its border; then the angle L C M is equal to the apparent semidiameter of the sun, that is $16'$; and if we make the focal distance L C $= f$, we have the semidiameter of the focus L M $= f$ tan. $16'$. But the tangent of $16'$ is very nearly $= \frac{1}{216}$; therefore the semidiameter of the focal circle is very nearly the 216th part of the focal distance. Hence we derive a rule for finding the intensity of the heat in the focus of a burning glass; since all the rays which fall on the glass are collected within the focal circle, the intensity of the heat in that circle is to the intensity of the heat falling on the glass in the ratio of the area of the glass to that of the focal circle. But circles are to each other as the squares of their diameters; whence, calling the diameter of the glass d, and supposing the light falling on it to be represented by unit, the intensity of the light or heat within the focal circle is d^2 divided by $(\frac{1}{108})^2 f^2$; or it is directly proportional to the square of the diameter of the glass, and inversely to the square of the focal distance. For a spherical lens, convex on both sides, the diameter of the focal circle is one-eighth of the thickness of the lens; but though it cannot be less than this quantity, in imperfect glasses it will considerably exceed it. *See* LENS, BURNING GLASS.

FO'DDER. (Germ. futter.) In Agriculture, the food given to quadrupeds, which consists of the stems and leaves of plants, such as the culmiferous stems of the grasses, the haulm of legumes, potatoes, &c.; or, in short, whatever is given as the ordinary food is designated fodder; whereas corn, beans, and other articles, which present nourishment in a more concentrated form, are not included under the term fodder, but rather known as solid food.

FODDER, is the name of a weight formerly used in the weighing of lead: it was of various magnitudes, but most commonly amounted to about 2400 lbs.

FOE'TUS. (Lat. feo, *I bring forth*.) From about the fifth month after pregnancy till the period of its birth, the child in the womb of its mother is termed a *fœtus*.

FOG. (Dan. fog.) In Meteorology, a dense vapour near the surface of the land or water. Fogs, in general, are the consequence of the nocturnal cooling of the atmosphere. The air, by its rapid cooling, becomes surcharged with moisture; a part of which, being precipitated in the form of a cloud, gives rise to the ordinary fog. During the day the heat of the sun generally disperses the fog, because the quantity of moisture which the air is capable of holding becomes more considerable in proportion as its temperature is increased.

In calm weather the surfaces of rivers, lakes, &c. are frequently in the morning covered with fog. The reason is this. During the night the air is colder than the water; the strata of air in contact with the water are consequently heated, and become saturated with moisture. The mixture of the vapour with the air, together with its elevation of temperature, renders the air specifically lighter. It rises in consequence, and mixing with the cold air in the superior strata, is cooled, and precipitates its moisture. The cloud or fog resulting from this precipitation can only rise to a small height, because the uniformity of temperature is soon restored. Hence it is easy to see how winds, or a great agitation of the air, prevent the formation of fogs over the surface of water. In the equinoxial regions, fogs sometimes continue during a considerable part of the year. Humboldt relates that Lima is often covered with a fog half the year, especially in the mornings and evenings; and that along the whole of that coast fogs supply the place of rain, which is extremely rare. In the polar seas thick fogs often prevail, even during the warmest months; and they are so dense that objects frequently cannot be distinguished at the distance of a few yards.

Sometimes, though rarely, fogs occur of which the cause is not very well understood. In 1783, the whole of

Europe was covered with a dense fog during nearly two months. On the 22d of May, 1822, about 5 o'clock in the afternoon, a fog covered Paris and the neighbourhood, which had the odour of nitrous gas: it continued about an hour. Dry fogs, or those in which no moisture is present, are supposed to be the vapours and ashes ejected by volcanos, and diffused in the atmosphere by the winds.

FOIL. (Fr. feuille, or Lat. folium, *a leaf*.) This term is generally applied to varnished metal. Common foil is manufactured as follows: — A copper plate, covered with a thin layer of silver, is rolled out into sheets under the flatting mill; the silver surface is then highly polished or covered with a colourless varnish. The *coloured foils* are similarly prepared with coloured varnishes.

FOLD. (Sax. ꝼealꝺe.) A temporary enclosure for keeping cattle or other agricultural animals together, either for the purpose of protection during night, or jointly for protection and feeding. Sometimes, also, sheep are folded for the purpose of manuring. The barrier of which folds are constructed is commonly wooden hurdles; but sometimes, when the fold is only to contain ewes and lambs, netting stretched between posts is made use of, there being a strong rope fixed to the lower parts of the posts close to the ground, to which the under edge of the netting is attached, while its upper edge is attached to a rope stretched along the tops of the same posts. The practice of folding sheep on naked fallows, with a view to manuring them, is still common in several parts of England; but the more improved sheep farmers consider that it deteriorates the wool, and impedes the fattening of the sheep, by keeping them for the greater part of every night wholly without food.

Fold. In Painting, the doubling or lapping of one piece of drapery over another.

FO'LIAGE. (Lat. foliatus, *leaved*.) In Architecture and Sculpture, a group of leaves of plants and flowers, so arranged as to form architectural or sculptural ornaments; as in friezes, panels, and also in the capital of the Corinthian order.

FO'LIATE, in the doctrine of curve lines, is the name given to a curve of the third order, defined by the equation $x^3 + y^3 = axy$. It is one of the species of defective hyperbolas, having one asymptote and two infinite branches; and its figure has some resemblance to a leaf, whence the name. (See *Newton's Enumeratio Linearum Tertii Ordinis*.)

FO'LIA'TION. The manner in which the nascent leaves are arranged within a leaf-bud.

FO'LIO (Ital. *a leaf*), in Account-books, signifies page. Thus folio 7, — written abridgedly fo. 7, — denotes the seventh page; Folio recto, or F° R°, signifies the first page; Folio verso, or F° V°, the second page of a leaf. A book in folio, or simply a folio, is that where the sheet is only folded in two, each leaf making half a sheet.

FOLI'OLUM. A leaflet borne upon the axis of a leaf.

FO'LKMOTE, among our Saxon ancestors, signified any popular or public meeting of all the folk or people of a place or district; for instance, of all the tenants at a court leet or court baron, or of all the freemen of the county, or of all the barons of the kingdom. Antiquaries are, however, by no means agreed as to the nature of the folkmote; some considering it an institution of great, others of minor importance. (See *Somner's Anglo-Saxon Dictionary; Brady's Introduction to Old English History; Fabian's Chronicles;* and *Wilk. Leg. Anglo-Sax.*)

FOLLI'CULUS. A one-celled, one or many-seeded, one-valved superior fruit, dehiscent by a suture along its face, and bearing its seeds at the base, or on each margin of the suture; differing from the legumen in having but one valve instead of two.

This term has also other significations; viz. 1. According to Linnæus, any kind of capsule. 2. The cases bearing the reproductive organs of *Equisetaceæ*. 3. According to Gærtner, a double, one-celled, one-valved, membranous, coriaceous capsule, dehiscing on the inside, and either bearing the seed on each margin of its suture, or on a receptacle common to both margins; as *Asclepias*, &c. 4. According to Willdenow, any oblong pericarpium bursting longitudinally on one side, and filled with seeds; as *Vinca*.

FO'MALHAUT. A star of the first magnitude in Piscis Australis.

FOMENTA'TION. Local bathing with hot water, or medicated decoctions.

FONT. (Lat. fons.) In Architecture and Sculpture, a vessel generally of stone or marble for containing the water of baptism in the Christian church. Some of the early fonts are extremely beautiful, and wrought with extraordinary richness of decoration. The singular inscription which is frequently found on the walls of baptisteries occurs also occasionally on ancient fonts — NIΨON ANOMHMATA MH MONAN OΨIN; which reads equally forwards or backwards, admonishing the reader to cleanse himself from evil deeds not less than use the outward ceremony of baptism.

FO'NTANEL. The interstice, or *mould*, as it is often called, which exists at birth between the frontal and parietal bones: it is closed by bony matter about the end of the third year.

FOOD. All substances susceptible of digestion and assimilation may come under the denomination of *food;* but the proximate principles of organic bodies on which their nutritive powers depend are comparatively few. Hence, although the articles employed in different countries for the support of animal life are almost infinitely various, their sustaining powers may be referred to certain substances capable of being separated and indentified by chemical analysis and tests. Amongst the proximate elements of vegetable food gluten and its modifications, starch, gum, sugar, and lignin or woody fibre, are by far the most important; and amongst those of animal food albumen, gelatin, and their modifications, together with fats and oils, which are common to both kingdoms of nature.

To illustrate the actual simplicity of our food as compared with its apparent multifariousness and complexity, it may suffice to state, that wheat and almost all the esculent grains consist principally of starch and gluten; that the same ingredients are found in many fruits and roots; that sugar, gum, or a relation of gum which is called vegetable jelly, together with minute traces of aromatic principles which give flavour, and more or less abundance of water, and of vegetable acids, are the chief component parts of apples, pears, peaches, currants, gooseberries, and all analogous tribes of fruits; a very few also contain oil. Then, as regards *animal* food, the muscular fibres of various animals closely resemble each other in composition and nutritive power; in some cases texture merely, and in others minute additions of foreign matters, confer upon them their relative digestibilities, and their different aspects and flavours: albumen or fibrine, and gelatin, small proportions of saline bodies, and a large quantity of water are found in them all.

It often happens that the truly nutritious part of food is so combined with or protected by indigestible matters, as to escape the solvent powers of the stomach, unless previously prepared and modified by various chemical and mechanical agents. Indurated woody fibre, for instance, or *lignin*, as chemists call it, will often resist the joint action of the stomach and bowels, and pass through the alimentary canal with scarcely any alteration. The husks of many seeds and fruits are composed almost exclusively of this material. This is the case with the kernels of the apple, pear, &c.; the seeds of the currant, gooseberry, melon, and so on; the skin or husk of peas, beans, &c., and of wheat, barley, and oats; so that unless this woody part is either broken down by the teeth, or previously removed, the food which it envelopes is protected from the solvent action of the secretions of the stomach. This is in some respects a wise and curious provision in nature; for birds in this way become the carriers of seeds, which pass through them not only undigested, but even retaining their vegetative powers; and in this way uninhabited and sterile portions of the globe may gradually become clothed with verdure, and shrubs and trees. Bones are highly nutritive; but unless broken into very small fragments by the masticatory powers of the animals which eat them, they too would elude digestion. In reference, however, to the food of man, much of its digestibility and nutritious power is referable to the important chemical operations preparatory to its use which are carried on in the kitchen: in other words, cookery is essentially a chemical art; and substances totally unfit, in their raw state, for reception into the stomach, are rendered palatable, digestible, and nutritious, by the skill of the cook. And here salt, and a variety of *condiments*, as they are called, and which are aromatic and stimulant substances chiefly of vegetable origin, play an important part; nor must the mere effect of heat be overlooked, for it is most important. Meat, by boiling and roasting, is not only softened in its fibre, but new substances are generated in it. Among these a peculiar extractive matter, and *osmazome*, or the principle which gives an agreeable flavour and odour to dressed meat, are especially recognized. Nor are the changes which vegetables suffer under the influence of heat less obvious.

There is another important point in the history of our food, namely, its *ultimate composition*. We have spoken of starch, sugar, gum, albumen, and other substances, as the *proximate* principles upon which we live; but what is the *ultimate* constitution of these secondary products, what are their true *elements?* It is curious that four *elements* only are principally concerned in the production of our food. These are carbon, hydrogen, oxygen, and nitrogen. Among vegetable substances gluten (including vegetable albumen) is the only one which abounds in nitrogen; gum, sugar, starch, and the rest are constituted of carbon, hydrogen, and oxygen only; and what is very remarkable is, that in all these important principles, and also in lignin, the oxygen and hydrogen bear to each other the same relative proportions as in water, so that they may be figuratively described as compounds of *charcoal* and *water*. Now there are two

very curious points in reference to that part of the chemical history of our food which has been adverted to: the one is, that no animal can subsist for any length of time upon food which is destitute of nitrogen; and the other, that a certain mixture of different kinds of food is absolutely essential. An animal fed *exclusively* on starch, or sugar, or albumen, or jelly, soon begins to suffer in health; peculiar diseases make their appearance, and his existence is painful and brief; but mix these together, and occasionally modify their proportions, and he then thrives and fattens. Magendie's experiments on this subject, together with those of Tiedemann and Gmelin, well illustrate this fact. Thus, geese fed upon gum died on the 16th day, those fed upon starch on the 24th, and those fed on boiled white of egg on the 46th: in all these cases they dwindled away and died as if of starvation.

Habit, as is well known, will do much in accustoming the stomach to particular descriptions of food; many persons live exclusively, or almost so, on vegetable, others on animal matters, and particular kinds of diet are forced on the inhabitants of many regions of the globe; but, as far as we are concerned, a due mixture of vegetable and animal matter is not only most palatable, but most conducive to health. Nothing is fit for food which has not already undergone organization; and *water*, though an essential part of the food of all animals, is obviously not in itself nutritious, though it performs the extremely important function of dissolving nutritive matter, so as to render it conveyable by the lacteals and other absorbents into the blood. No compound then of nitrogen, hydrogen, carbon, and oxygen, which can be formed artificially, can constitute food. Air, water, and charcoal, though involving the *elements* of our nutriment, are themselves unfit for our support; and it is only by passing through the hidden processes which are carried on in the vessels of living things, that they are so recombined and modified as to be rendered capable of supporting animal life. It is the vegetable world which commences this wonderful operation. Plants absorb their nutriment from the air and from the soil; they assimilate inorganic as well as organic matter; they become the food of the graminivorous tribes, and from these man derives the great bulk of his animal food.

In speaking of the composition of food, that of *milk*, the most important of all food, must not be forgotten; in it nature has wonderfully provided a mixture which, though secreted by an animal, partakes also of the nature of vegetable food, and it presents a perfect analogy to that combination of vegetable and animal matter which has been mentioned as most congenial to the palate and stomach. The albumen or *curd* of milk is a highly elaborated animal principle, abounding in nitrogen, yet, from its attenuated and soluble state, easy of digestion. A second principle of milk is what is termed *sugar of milk*; in composition and properties it resembles a vegetable product, and is intermediate between gum and sugar. The third component of milk is *butter*, partaking of the nature of vegetable oil and animal fat; there are certain saline and acid substances in small proportion; and all these matters are either dissolved or suspended in a large relative proportion of water.

I. Table showing the average quantity of nutritive matter in 1000 parts of several varieties of animal and vegetable food.

Blood	215	Wheat	950	Apples	170
Beef	260	Rice	880	Gooseberries	190
Veal	250	Barley	920	Cherries	250
Mutton	290	Rye	792	Plums	290
Pork	240	Oats	742	Apricots	260
Brain	200	Potatoes	260	Peaches	200
Chicken	270	Carrots	98	Grapes	270
Cod	210	Turnips	42	Melon	30
Haddock	180	Cabbage	73	Cucumber	25
Sole	210	Beet root	148	Tamarind	340
Bones	510	Strawberries	100	Almonds	650
Milk	72	Pears	160	Morels	896
White of egg	140				

The above table represents the relative proportion of solid digestible matter contained in 1000 parts of the different articles of food which are enumerated. When blood, for instance, is evaporated to dryness, at a temperature not exceeding 212°, the residue amounts to 215 parts in 1000, and may be regarded as almost entirely composed of digestible matters; it consists of albumen and colouring matter, with small proportions of saline substances. The different kinds of meat were dried in the same way. The loss of weight during their desiccation is almost wholly referable to water; and the dry residue composed of albumen or fibrine, with some gelatine, and perhaps traces of fat and of saline matters, represents the true nutritive value. Upon an average, therefore, the nutritive matter in a pound of meat is not more than four ounces. This, however, only applies to raw meat; for when dressed a considerable portion of its constituent water is often dissipated. The nutritive matter of wheat is chiefly starch and gluten, and in this species of grain the gluten is in much greater relative proportion to the starch than in barley, oats, or rye. In rice there is little else than starch. There can be little doubt that the great value of wheat as an article of food depends upon this excess of gluten, which is a nitrogenous substance, and has not inaptly been termed the vegeto-animal principle. In the esculent roots, such as carrots, &c., but especially turnips, sugar is the leading nutritive matter; and the common fruits contain sugar, gum, albuminous matter, and acids, together with a highly attenuated form of woody fibre, or lignin, which, in that state, is probably digestible.

The following table shows the ultimate composition of those proximate principles which have been above adverted to as constituting the nutritive part of food:—

II. Table showing the ultimate elementary composition of 1000 parts of the following proximate principles of animal and vegetable food.

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.
Albumen	516	76	258	150
Gelatin	483	80	276	161
Fat	780	122	98	
Curd of milk	609	73	116	203
Sugar of milk	454	61	485	
Gluten	557	78	220	145
Starch	438	62	500	
Gum	419	68	513	
Sugar	444	62	494	
Lignin	500	56	444	

FOOLS, FEAST OF. A festival anciently celebrated in almost every church and monastery of France on New Year's Day, in which every absurdity and even indecency was practised. It was equivalent to the Saturnalia among the Romans, whence indeed it is said to be derived. This festival received some modifications in the different districts where it was celebrated, and acquired various designations according to the multifarious ceremonies of which it consisted. Thus it was termed "la fête des diacres souls, des cornards, des innocents," &c. Several bishops and councils attempted, though in vain, to abolish this festival; but at length about the 15th century it became less generally observed, and soon after fell into almost total disuse, though its characteristic absurdities are still maintained in the Carnival of the present times. For full details on the Feast of Fools see the *Encyclopedie des Gens du Monde*, under the head "Fous (Fête des)," and the authorities there referred to.

FOOL'S PARSLEY. An umbelliferous plant, common in waste ground, and so called from its resembling parsley enough in appearance to deceive ignorant persons. It is a poisonous plant, acting like hemlock upon the human system; and is easily known by the involucels having each three leaflets, which are always placed next the circumference of the umbel. It is the *Æthusa cynapium* of botanists.

FOOT. (Germ. fuss.) A measure of length. As this term is employed in almost all languages as a linear measure, it has doubtless been derived from the length of the human foot. Though the denomination is the same, the measure itself varies considerably in different European countries. In all of them, however, it is divided, like the English foot, into twelve equal parts or inches. *See* MEASURES.

FOOT. In Prosody, a measure consisting of two, three, or four syllables, long, short, or long and short. All the combinations of which these numbers are susceptible amount to twenty-eight; and such is accordingly the number of feet enumerated by Greek and Latin prosodists, according to the following table:—

⏑⏑	Pyrrhich	–⏑–⏑	Ditrochæus
– –	Spondee	⏑–⏑–	Diiambus
–⏑	Trochee	–⏑⏑–	Choriambus
⏑–	Iamb	⏑––⏑	Antispastus
⏑⏑⏑	Tribrachys	⏑⏑––	Ionicus a minore
–––	Molossus	––⏑⏑	Ionicus a majore
–⏑⏑	Dactylus	–⏑⏑⏑	Pæon primus
⏑⏑–	Anapæst	⏑–⏑⏑	Pæon secundus
⏑–⏑	Amphibrachys	⏑⏑–⏑	Pæon tertius
–⏑–	Amphimacer	⏑⏑⏑–	Pæon quartus
⏑––	Bacchæus	⏑–––	Epitritus 1
––⏑	Palimbacchæus	–⏑––	Epitritus 2
⏑⏑⏑⏑	Proceleusmaticus	––⏑–	Epitritus 3
––––	Dispondeus	–––⏑	Epitritus 4

But by rejecting those which are merely reduplications of disyllabic feet (Proceleusmaticus, Dispondeus, Ditrochæus, and Diiambus), the number is reduced to twenty-four; and by also striking off those which are compounds of disyllabic feet (Choriambus, Antispastus, two Ionics, four Pæons, and four Epitrites), the number of simple feet becomes twelve only. *See* RHYTHM.

FOO'TINGS. In Architecture, the spreading courses at the base or foundation of a wall.

FO'RAGE, in Military affairs, signifies the provisions brought by the troops into the camp for the sustenance of the army, &c. during a campaign.

FORA'MEN. (Lat. foro, *I pierce.*) In Anatomy, a

small opening. The *foramen ovale* is an opening between the two auricles of the heart of the fœtus, which closes at birth.

FORA'MEN. In Botany, the opening that exists in the integuments of every ovulum.

FORAMI'NIFERS, *Foraminifera*. (Lat. foramen, fero; *I bear*.) A name applied by D'Orbigny to a tribe of minute shells, which he believed to be formed by Cephalopods; they are now proved to belong to a lower-organized class of animals. *See* SYMPLECTOMERANS.

FORCE, in Mechanics, is that which produces motion, or a change of motion. Forces may be of different kinds; but they are all compared and measured by the quantities of motion which they respectively produce in a given time: in fact, we know nothing whatever of forces excepting through their effects.

In order to determine what will be the effect of a force upon any given mass of matter, three circumstances respecting the force are necessary to be known; namely, its intensity, the place where it acts or its point of application, and its direction. Its intensity is proportional to the space through which the unit of mass is moved in the unit of time; therefore, since the space described is proportional to the velocity (supposed uniform), if the mass remains constant a double force will produce a double velocity; and if the velocity is constant, a double mass must be urged by a double force. Hence the force of the body is proportional to the mass and to the velocity conjointly. Thus let m and m' be two masses, or the quantities of matter in two bodies, and v and v' be the velocities with which they respectively move in consequence of the two forces whose intensities are f and f; then f is proportional to $m\ v$, and f' to $m'\ v'$.

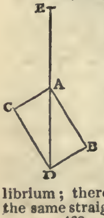
When a body is acted upon by more forces than one, it is obvious that it will not move in the direction or with the velocity due to one of the forces alone, but in a direction and with a velocity due to their collective influence. The effect produced by the joint action of the several forces is called their *resultant;* and it is determined both in magnitude and direction by the following theorem, celebrated under the name of the *Composition of Force:* — "If the lines which each of two forces acting singly would have caused a body to describe in a given time make any angle whatsoever with one another, the line which the body will describe in that time, when both the forces act upon it at the same instant, is the diagonal of the parallelogram under the two first-mentioned lines." Thus, let a body at A be acted upon by two forces at the same instant, one of which, if acting alone, would cause

it to move over the line A B in a given time, and the other acting alone would cause it to move over the line A C in the same time; then the direction of the motion resulting from the action of both forces will be that of the diagonal A D of the parallelogram A B D C, and at the end of the given time the body will be found at D. The theorem may be derived from the principle that the velocity of the body in one of the directions is not changed by the force impelling it in the other; but of this principle it is not easy to give a satisfactory demonstration, without introducing considerations drawn from the resources of the higher mathematics. (See *Poisson*, *Mecanique*, tome 1.)

It is obvious that by means of this theorem the resultant of any number of forces whatever may be found; for after finding the resultant of any two of the forces, we may conceive them to be removed, and their resultant substituted, when the resultant of this and the third force will be the resultant of three of the forces. This last resultant may then be combined with a fourth force, and so on till the whole of the forces have been included. This construction is called the polygon of forces.

As the forces represented by the straight lines A B and A C are *compounded* into a single force, represented in intensity and direction by A D; so any given force may be *resolved* into two others, such that the straight lines by which they are represented form the two sides of a parallelogram of which the line representing the given force is the diagonal. This composition and resolution of forces is of constant application in Mechanics.

If a body impelled at the same time by three forces re-



main at rest, these forces are proportional to the three sides of a triangle formed by drawing straight lines parallel to their directions. For, let the three forces acting on the point A be respectively represented in intensity and direction by the three straight lines A B, A C, A E; then by forming the parallelogram A B D C, and drawing the diagonal A D, we have the two forces represented by A B and A C equal to the single force represented by A D and acting in the direction A D. But the point A is by hypothesis in equilibrium; therefore A D must be equal to A E, and in the same straight line with it; whence, since B D is equal to A C, the three forces by which the point A is kept in equilibrium are respectively proportional to the three sides A B, B D, and A D of the triangle A B D.

Let the three forces be respectively denoted by P, Q, and R; then, the sides of a triangle being proportional to the sines of the opposite angles,

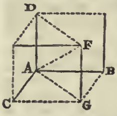
$$P : Q : R :: \sin. ADB : \sin. DAB : \sin. ABD.$$

But by reason of the parallel lines the angle A D B is equal to D A C, and A B D being the supplement of C A B their sines are equal; whence

$$P : Q : R :: \sin. DAC : \sin. DAB : \sin. CAB.$$

From this we infer that if a point A be kept in equilibrium by the action of three forces P, Q, and R, each of these forces is proportional to the sine of the angle formed by the direction of the two others. It is also a consequence of this proposition that if three forces be in equilibrium they must all act in the same plane, and any two of them must be greater than the third.

The resultant of three forces X, Y, Z, applied to the same point A in space, and severally represented in mag-



nitude and direction by the straight lines A B, A C, A D, is represented by A F, the diagonal of the parallelepipedon, of which the sides are A B, A C, and A D. For the two forces X and Y, which are represented by A B and A C, the two sides of the parallelogram A B G C will have for their resultant a force P, represented by A G, the diagonal of this parallelogram. And because A D is equal and parallel to G F, the figure A D F G is a parallelogram; and consequently the two forces P and Z, represented by A G and A D, will have for their resultant a force R, represented by A F, the diagonal of the parallelogram A D F G, which is also the diagonal of the parallelepipedon.

From this theorem it follows that any force whatever R can always be decomposed into three others, X, Y, Z, respectively parallel to three straight lines given in space, provided that no two of them be parallel; and if each of the three given lines be at right angles to the plane of the other two, and the angles which A F (the direction of the given force R) makes respectively with A B, A C, A D (the directions of the forces X, Y, Z) be denoted by a, b, c, we have then, evidently,

$$X = R \cos. a,\ Y = R \cos. b,\ Z = R \cos. c,$$

the three angles a, b, c, being connected by the relation

$$\cos.^2 a + \cos.^2 b + \cos.^2 c = 1.$$

In those investigations in mechanics where a number of forces are concerned, it is usual to resolve them all into three forces parallel to three rectangular co-ordinates; when the resultant of the three sets of rectangular forces will evidently be the common resultant of all the forces. If F, F′, F″, F‴, &c. be the forces; a, a', a'', a''', &c. the angles which they make with one of the three axes; b, b', b'', b''', &c. the angles which they make with another of the axes; and c, c', c'', c''', &c. the angles which they make with the third; and X, Y, Z be the three rectangular forces which are the sums of the components of all the original forces, F, F′, F″, F‴, &c.; then,

$$X = F \cos. a + F' \cos. a' + F'' \cos. a'' + F''' \cos. a''' + \&c.$$
$$Y = F \cos. b + F' \cos. b' + F'' \cos. b'' + F''' \cos. b''' + \&c.$$
$$Z = F \cos. c + F' \cos. c' + F'' \cos. c'' + F''' \cos. c''' + \&c.$$

As the three forces X, Y, Z are not situated in the same plane, and can therefore never be in equilibrium so long as any one of them has a real value, in order that the body may remain at rest under the action of all the given forces F, F′, F″, F‴, &c., it is necessary that the three conditions be fulfilled; namely, $X = 0$, $Y = 0$, $Z = 0$.

Forces have different denominations according to the manner in which they act; thus we have *Accelerating Forces*, *Central Forces*, *Parallel Forces*, *Uniform* and *Variable Forces*, &c. *See* ACCELERATION, CENTRAL FORCE, PRESSURE, &c.

Accelerating Force. — An accelerating force is that which continues to act upon a body after it has been put in motion; whence the body moves with a variable velocity, and, when the intensity of the force is constant, receives equal increments of velocity in equal intervals of time. We have a familiar example of an accelerating force of this kind in terrestrial gravity, under the action of which heavy bodies dropped from a height fall to the ground with a constantly accelerated velocity.

When a body is urged by an accelerating force, the relations between the force, the velocity, the space passed over, and the time, are expressed by three equations, which are called the equations of motion, and may be investigated as follows: —

Let t denote the time from the commencement of the motion, v the velocity acquired at the end of the time t, and a the space described by the moving body. During

an infinitely small time, $d\,t$, the velocity may be regarded as uniform, and the increment of the space in this time is $d\,x$; therefore, since the space described by a uniform velocity is proportional to the velocity and time conjointly, we have $d\,x = v\,d\,t$. (1.)

Let ϕ represent the force which accelerates the body at the end of the time t; since the motion may be regarded as uniform during an infinitely small time, if v be the velocity at the end of the time t, then $v + d\,v$ is the velocity at the end of the time $t + d\,t$, and therefore $d\,v$ is the increment of velocity due to the force ϕ during the time $d\,t$. Assume F = a constant force which produces a velocity = V in the portion of time which is assumed as unity (for instance, one second); then the velocity generated by F in the time $d\,t$ will be $V\,d\,t$. Now, since ϕ produces the velocity $d\,v$ in the instant of time $d\,t$, and F produces the velocity $V\,d\,t$ in the same instant, and since the forces are proportional to the impressed velocities, we have therefore $\phi : F :: d\,v : V\,d\,t$. Now, suppose F to be the unit of force, and V the unit of velocity, and the proportion becomes $\phi : 1 : d\,v : d\,t$; whence $d\,v = \phi\,d\,t$. (2.)

Differentiating the equation $d\,x = v\,d\,t$ on the supposition that $d\,t$ is constant, and substituting the resulting value of $d\,v$ in (2), we obtain $d^2\,x = \phi\,d\,t^2$. (3.)

The three differential equations now found, which define the motion of a body urged by an accelerating force, are usually exhibited as follows: —

$$v = \frac{d\,x}{d\,t},\ \phi = \frac{d\,v}{d\,t},\ \phi = \frac{d^2\,x}{d\,t^2}.$$

On eliminating $d\,t$ from the first and second, we obtain a fourth, $v\,d\,v = \phi\,d\,x$, which it is often convenient to employ. These equations, which may be considered as the foundation of the science of dynamics, are easily integrated when the accelerating force ϕ is supposed to be uniform. Their immediate integrals, taken on this supposition, give the equations of the motion, *in vacuo*, of bodies accelerated by gravity, the discovery of which sheds so much lustre on the names of Galileo and Newton. *See* GRAVITY.

Living Force, or *Vis Viva*, is a term frequently used by the mathematicians of the last century to denote the action of a force when it is estimated in such a manner as to be proportional to the square of the velocity. It has been stated above that when the masses moved are equal, the moving forces are respectively as the velocities. But the effect of a body in motion may be considered under different aspects. If we conceive the effect to be measured by the *time* which elapses before a resistance of uniform intensity reduces the body to rest, then the force is proportional to the velocity simply; but if, on the other hand, we conceive the effect to be measured by the distance passed over by the moving body while subjected to the uniform resistance, then the force will be proportional to the square of the velocity. These two measures may both be considered as correct; and they are not inconsistent when rightly understood. A warm controversy, however, arose on the subject, in which some of the most distinguished mathematicians of the time took a part; but when the ambiguity arising from the use of the word *force* in different senses was cleared away, both sides were found to be in the right. (See *Playfair's Dissertation, Ency. Brit.*)

FO'RCER. In Mechanics, a solid piston, applied to pumps for the purpose of producing a constant stream, or of raising water to a greater height than it can be raised by the pressure of the atmosphere. *See* PUMP.

FO'RCIBLE ENTRY AND DETAINER. In Law, a species of offence against the public peace, committed by violently taking or keeping possession of lands and tenements with menaces, arms, and force, and without authority of law, to the hinderance of him who has right of entry. The remedy is, under several statutes, by action; by the intervention of justices of the peace, who have power, on view of the force, to make a record of it, and commit the offender.

FO'RCING. In Horticulture, the art of accelerating the growth of plants, so as to obtain fruits or flowers at seasons when they are not produced naturally in the open air. The practice appears to be as old as the Romans; since Pliny informs us that Tiberius, who was fond of cucumbers, forced them to bear fruit in the winter time by growing the plants in boxes kept in houses with talc windows, which boxes were wheeled out during fine days, and always taken into the house again at night or in cold weather. From some epigrams of Martial it has been thought that the Romans had both vineries and peach-houses; talc (*lapis specularius*) being used instead of glass. In England forcing appears to have been practised from a very early period; radishes having been raised on dung beds covered during night by wheat straw from time immemorial, and cherries having been forced on wooden walls or boarded espalier rails, heated by linings of hot dung at the back, at least from the time of Charles II., and probably long before, since it is certain that melons and cucumbers were grown at Hampton Court for the royal table in the time of Henry VIII. At the present time forcing is carried on in Britain, and in analogous climates throughout Europe and North America, chiefly under glass roofs. Structures for forcing are known, as frames, pits, and houses, all of which have glass roofs; but there are also structures for forcing without glass roofs, such as cellars and sheds for growing mushrooms in the winter season; and also seakale, rhubarb, blanched succory, and such other stalks or leaves of plants as are eaten in a blanched state, and consequently do not require much light. The art of forcing plants must never be confounded with the art of growing them in artificial climates, though in both cases the principles by which the gardener proceeds are essentially the same; viz. the art of imitating nature. The chief difficulty of accomplishing this in forcing is the want of light; and hence the earlier in the season that any forced crop is produced, the greater is its deficiency in colour and flavour. Gentle forcing, so as, as it were, to anticipate spring, and bring fruits so far forward as to enable them to profit from the full influence of the sun during our short summers, may be considered as a real advantage, which will never cease to be sought for; and as a case in point we will mention the grape, the fruit of which is never brought to perfection in this country unless the plants have been partially forced. To force, in any country, the fruits which come to perfection in the open air in that country, such as the apple, pear, cherry, gooseberry, &c., in Britain, and analogous climates on the Continent, can only be considered as a luxurious waste of wealth, which would be more elegantly and usefully expended in forcing the fruits or in growing the flowers of warm climates, which can only be brought to perfection in this country under glass. Even this kind of forcing is open to criticism, on what may be called the greatest enjoyment principle. For example, there are certain fruits, such as the mango, the dourion, mangosteen, &c., which could only be grown in this country at an enormous expense, and probably when grown would not be worth eating; while there are certain other fruits, such as the pine apple and the banana, which can be grown in this country at a moderate expense to almost as great a degree of perfection as in their native climate. To attempt growing the former kind of fruit merely for the sake of overcoming the difficulty of doing so, we hold to be in bad taste; though we allow that some good might result from it to horticultural science, by calling forth the skill and ingenuity of gardeners: this, indeed, may be considered as the only permanent benefit which will be produced by forcing. With the progress of intercommunication by means of steam and railways, it seems highly probable that the fruits of warm climates will cease altogether to be cultivated in cold climates; with the exception of some, such as the cucumber, melon, banana, fig, &c., which require to be eaten when freshly gathered. Even at the present time, with the comparatively imperfect communication which exists between this country and the south of Spain and the West Indies, there is no reason why we should not be supplied with pines, grapes, and oranges throughout the year. The hot-houses of gardens will then be chiefly employed for the culture of exotic flowers and exotic plants of curiosity.

FORCING PUMP. *See* PUMP.

FORE. The sea term for the part of the ship near the head.

FORE AND AFT, implies lying in the direction of the head and stern; also, the whole of the vessel generally.

FO'RECASTLE. The upper deck near the head; this was formerly much raised, hence the name.

FO'REFOOT. A piece of timber at the fore extremity of the keel.

FO'RELAND. In Fortification, a piece of ground between the wall of a place and the moat. Foreland is also used synonymously with promontory, cape, headland, &c., as the North Foreland in Kent.

FORESHO'RTENING. In Painting, the representation of any object presented obliquely to the eye.

FO'REST. (In Germ. *forst*, from whence our word is probably derived, although the ultimate etymology is unknown. The Saxon word *hurst*, with which the names of so many places in the South of England terminate, has probably the same origin. In the primitive meaning of the word it probably signified an enclosed space, from which intruders were excluded: hence some have derived it from the Latin *foris*.) An extensive surface, covered naturally by trees and undergrowth; as opposed to a plantation, which has been made by art. In former times the greater part of every country in the temperate parts of Europe was undoubtedly covered with forest; and these by nourishing wild animals of every description, particularly wild swine, afforded a principal part of the food of man. With civilization, however, they gradually disappeared before the spread of extensive pastures or arable land. In every country a large portion of the forests belonged to the government, and formed a main source of its revenue. This is still the case in France and Germany, and till lately it was also the case to a

certain extent in Britain. Hence extensive tracts in England still bear the name of forest, though they are now in a state of cultivation, and in a great measure without trees. Many ancient laws and customs are recorded in books respecting the forests of the crown; but at present, as there are only three or four government forests in Great Britain, these laws and customs are of very little consequence, excepting to those living in their immediate neighbourhood.

Many of the spots which in England bear the name of forest have no appearance of having been covered with trees at any period since Britain became inhabited. The English forests (with the exception of the New Forest, of which the history is well known) are, however, so ancient that we possess no record of their origin. Their number has been reckoned at 68; another enumeration extends them to 76, but some of these are probably only parts of the same forest with different names. A forest is created by the king, by a commission issued out of the Court of Chancery; and, when its laws and ordinances have been framed and officers appointed, it becomes a forest by matter of record. Forests are grantable to subjects; but Savernake Forest in Wiltshire, held by the Marquis of Ailesbury, is, we believe, at present, the only instance. By the ancient forest laws, the Courts of the Forest were,— 1. The Justice Seat; a court of justice in eyre of the forest, held every third year to take cognizance of trespasses, pleas, and causes. (The last justice seat held in England for any other than mere formal business was for Windsor Forest in 1632.) 2. The Swain-Mote, or meeting of freeholders of the forest, held to receive and try presentments against offences in matters connected with the forest laws (in *vert* and *venison*); which presentments, 3. The Wood-Mote was held every forty days to receive and inquire into, but not to try. The principal officers of the forest were, its two justices in eyre, warden, regarders, foresters, rangers, &c.; some of which are still retained. The forest laws are of early date in England; those of King Canute are the earliest preserved. Under the first reigns after the Conquest their severity went on gradually increasing, and formed one of the chief oppressions under which the English suffered. But in 1224 the Carta de Foresta, granted by Henry III., fixed the limit of these aggressions. The capital punishments and mutilations of the former laws were rendered commutable for fines, and the king assented to a new perambulation of the forests: at which time, and subsequently, portions which had been illegally annexed to forests were disafforested. These portions are called Purlieus. In 1297, this charter was fully confirmed by Edward I. For an account of the existing forests of this country, see *Statistics of the British Empire*.

FO'RE-STAFF. A rude instrument, formerly used at sea for taking altitudes; and so called because in using it the observer turns his face to the object, instead of turning his back to the object, as is necessary in using the *back-staff*. Both these instruments have been superseded by the *sextant*.

FORESTA'LLING THE MARKET, in Law, is defined to be the buying up or bargaining for goods on their way to the market, in order to dispose of them at a higher price. But all mercantile practices having a tendency to enhance the common price have been, by a very sweeping intendment of the law, included within the same description. Forestallers are usually classed with ingrossers (those who bring up commodities to retail), and regraters (said to be derived from Fr. regratter, *to scrape over again*, from frauds practised in the dressing or scraping of second-hand cloth to sell again). Severe statutes have been passed at different times, from 5 & 6 Ed. 5. downwards, against this alleged offence. They were all repealed by 12 G. 3. c. 71. But it is said that the offence at common law still subsists: nor was it until 1827 (7 & 8 G. 4. c. 38.) that constables were expressly relieved from the (obsolete) duty of making presentments of forestallers at the quarter sessions. Although acts of this description have ceased to be subjects of criminal prosecution, it cannot be said that the public prejudice against them is yet worn out; although it is easily understood, and has been often proved, that in no way can the market for most commodities be rendered steady, the purchaser protected from the injurious consequences of excessive dearness, and the seller from those of glut and over-cheapness, as by the intervention of an intermediate body of wholesale dealers between the former and the latter.

FO'RFEITURE (Lat. forisfactura, *expulsion or outlawry*), has been defined to be a punishment annexed by law to some illegal act or negligence in the owner of real property, whereby he loses all his interest therein, and they go to the party injured as a recompence for the wrong which either he alone or the public with him hath sustained. Forfeiture is either civil or criminal. Civil forfeiture takes place when some alienation is made contrary to law, as in mortmain; or when a particular tenant alienes for a larger estate than he himself hath, as when tenant for life makes a conveyance in fee. Forfeiture for criminal causes takes place in treason or felony, and for one or two other offences. After judgment has been given, and the guilty party is said to be attainted, the forfeiture has a retrospective operation to the time when the offence was committed, so as to invalidate all sales and incumbrances that may have been effected since that time. Except in treason or murder, the forfeiture is only for the life of the offender; in treason and murder, however, the forfeiture extends to the disinherison of the heir.

FORFI'CULA. (Lat. forfex, *pincers*.) A Linnæan genus of insects, now forming a distinct order, *Dermaptera* (which see); and comprehending the subgenera *Labidura*, *Labia*, *Chelidura*, and *Forficula* proper, of which the labours of modern entomologists have made known numerous species; the common ear-wig (*Forficula auricularia*) is the type of this group of insects.

FORGE. (Fr.) The workshop in which iron is hammered and shaped by the aid of heat. The term is generally applied to the places in which these operations are carried on upon the comparatively small scale; the great workshops in which iron is made malleable for general purposes being called a *shingling mill*. A common forge consists of the hearth or fireplace, which is merely a cavity in masonry or brick-work well lined with fine clay or brick, upon which the ignited fuel is placed, and upon the back or side of which a powerful blast of air is driven in through the nozzle of a double-blasted bellows, which in a common forge is generally worked by a hand lever. Forges are sometimes constructed so as to be portable, when the bellows is most conveniently placed under the hearth; these are used in ships, and for various jobs on railways, &c.

FO'RGERY, in Law, is defined to be the fraudulent making or alteration of any record, deed, writing, instrument, register, stamp, &c., to the prejudice of another man's right. The statutes respecting this offence were consolidated by the act of 1830 (11 G. 4. and 1 W. 4. c. 66.), which also, after long and reiterated discussions, finally abolished the punishment of death in all cases, except for the forgery of wills and bills of exchange. This last remnant of the ancient code was finally removed in 1832 and 1837 by the statute 2 & 3 W. 4. c. 123., and 1 Vict. c. 84., by which the present punishments are fixed; varying from imprisonment for various terms to transportation for life, according to the classification of the offences comprehended under this general title.

According to a return contained in the report of the Constabulary Force Commission, 1839, the number of persons convicted of forging and uttering forged notes amounted to 104 in 1816, from whence it increased to 352 in 1820, fell to 134 in 1821, and since that time has diminished to a very small amount. The number of executions in 1812 was 23, in 1818 (the greatest) 24. The last execution for forgery took place in 1829.

FORLO'RN HOPE, in Military affairs, signifies certain men detached from several regiments or otherwise appointed to assume the initiative in an engagement; or, at a siege, to storm the counterscarp, mount the breach, &c. They are so called from the great danger to which they are inevitably exposed in such cases.

FORM. (Lat. forma.) In the Fine Arts, the bounding line of a material object. In Painting, the word is more generally applied to the human form. *See* BEAUTY.

FORMA'TION. A geological term, applied to a group of deposits or strata apparently referable to a common origin or period.

FO'RMEDON. In Law, a writ in the nature of a writ of right, which lies for him who has right to lands or tenements by virtue of an entail. (*See* FEE TAIL.) Formedon is in the *descender*, the *remainder*, or the *reverter*, according to the estate of the party who sues.

FORMI'CA. (Lat. *an ant*.) A Linnæan genus of insects, now the type of a very numerous and extensively distributed family (*Formicidæ*), belonging to the order *Hymenoptera*, and to that section which is negatively characterized by not being armed with a sting, and by not possessing any instrument for piercing the bodies of animals or the substance of plants for the purpose of oviposition.

The procreative economy of these well-known and most interesting insects is that to which all their wonderful habits and peculiarities are essentially related; and amongst those genera which the wisdom of Providence has ordained should form associations for the purpose of multiplying, preserving, and providing for their kind, the ants stand in a prominent and interesting rank, whether viewed as presenting some of the higher traits of animal instinct, or as a living evidence of an all-wise Intelligence, whose mute but incontrovertible orders are thus so implicitly and cheerfully obeyed.

In every species of insect the parents are relieved from the charge of providing for their offspring: they neither attend to their wants, nor defend them from harm in their immature and helpless state; and this, not from any deficiency of natural attachment, but from the brief period of their existence after having attained the state of maturity adapted for procreation; for at the close of this season the male generally dies before the eggs which

he has impregnated are excluded; and the female, whose last care has been to select a proper place for their development, soon dies after oviposition.

In the instincts and habits of which we are about to give a brief notice, the exception to the above rule is more apparent than real; for the individuals which manifest the feelings and discharge the duties of the mother are but foster-parents, and consist of females with undeveloped ovaria, and which are consequently unprolific, and are termed *neuters*. The males perish, and are destroyed by the neuters soon after having fulfilled their office; the prolific females, upon whom, on the contrary, the cares and affections of the neuters or workers are abundantly lavished, die soon after the ova are matured and excluded. This apparently threefold distinction of sex is peculiar to gregarious insects, as bees and ants.

Our intelligent countryman Gould describes five species of English ants; viz., 1. The hill ant (*Formica rufa*, Linn.); 2. The jet ant (*F. fuliginosa*, Latr.); 3. The red ant (*Myrmica rubra*, Latr.; *Formica*, Linn.); 4. The common yellow ant (*F. flava*, Latr.); and, 5. The small black ant (*Formica fusca*, Linn.).

In incipient societies of ants, as well as humble-bees (*Bombi*, Latr.) and wasps (*Vespæ*, Linn.), one female lays the foundation of the future colony, and the first brood which is hatched is very small. The larvæ, when first hatched, are hairy, and continue in the larva state twelve months or more.

The larvæ of the red ant do not, as other ants do, spin a cocoon when they assume the pupa state. The societies of ants, as also of other *Hymenoptera*, differ from those of the *Termites*, or white ants, in having inactive larvæ and pupæ, the neuters or workers combining in themselves the office of nurses, soldiers, and attendants. These undeveloped females never acquire wings. The female ants are furnished, at their first exclusion, with two pair of wings, which, after swarming in concourse with the males, they almost immediately cast. The office of the perfect or winged female is to provide a constant supply of eggs for the maintenance of the population. These are usually the least numerous part of the community. The office of the males (which are also winged during the time of swarming, and are extremely numerous) is merely the propagation of the species; after the season for this is past, they die. Sometimes the swarms of a whole district unite their infinite myriads, and, seen at a distance, produce a beautiful and curious effect, from the glancing of their silvery wings. The males and females quit the nests, their nursing places, about the end of July, or later, to the beginning or middle of September. The commotion which these winged individuals create in the nests, before they issue forth to fulfil their proper functions, is excessive. The whole swarm, when unhoused, alternately rises and falls with a slow movement to the height of about ten feet, the males flying obliquely, with a rapid zigzag motion, and the females, though they follow the general movement of the column, appearing suspended in the air, like balloons, seemingly with no individual motion, and having their heads turned towards the wind.

The noise emitted by countless myriads of these insects does not, however, exceed the hum of a single wasp; for their wings are weak, and bend to the wind, which carries the swarm irresistibly along. All the males, and the greater part of the females, are destroyed by becoming the prey of birds and fish, and other insectivorous creatures; for the loss of their wings, only lent them till the swarming season be past, renders them the most helpless and inactive beings, and they fall into the water in shoals, as well as bestrew the land. Dr. Bromley, while surgeon of the ship Clorinde, witnessed a scene which will give some idea of the multitudes of these insects which fall a prey to fishes alone.

"In September, 1814," he observes, "being on the deck of the hulk to the Clorinde, my attention was drawn to the water by the first lieutenant (since Captain) Haverfield, observing there was something black floating down with the tide. On looking with a glass, I discovered they were insects. The boat was sent, and brought a bucket full of them on board. They proved to be a large species of ant, and extended from the upper part of Salt Pan Reach out towards the Great Nore, a distance of five or six miles. The column appeared to be in breadth eight or ten feet, and in height about six inches, which I suppose must have been from their resting one upon another."

These ants were winged, so that they had probably been driven into the water by violent weather. When impregnation has taken place, the females alight, and then the neuters have been seen to seize and make prisoners of them, hanging upon their legs to detain them; leading them back to the formicary, and never quitting them till they are ready to lay their eggs, or become reconciled to state imprisonment, for such it really appears to be. They pay every attention to the royal prisoner's wants or comforts, leading her to the most genial spots in the nest, and regularly feeding her; but all this under a body guard, which, as her powers of locomotion become impeded by the enlargement of the ovaria, is gradually reduced to one sentinel, who is constantly relieved. The situation of this attendant is remarkable, being mounted on the queen-mother's body; and its office seems to be that of waiting till the eggs are produced, when it seizes and carries them off to the nurseries, or cells, prepared for this purpose. One of these queen ants will lay upwards of four or five thousand eggs in a year.

Gould gives an amusing account of the homage paid to the fertile mother of the future colony by the working ants. They will press round her, offer her food, conduct her by her mandibles through the difficult or steep passages of the formicary: they even carry her about their city. She is then suspended upon their jaws, the ends of which are crossed, and, being coiled up, she is packed so close as to incommode the bearers but little. When she is alighted, others surround and caress her, one after another tapping her on the head with their antennæ. They have a particular way of skipping, leaping, and standing upon their hind legs, and prancing with each other. These frolics they make use of in congratulation when they meet, and to show their regard for their queen. Some of them gently walk over her, others dance round her, and if separated from her will soon collect in a body and enclose her in the midst. When she dies, they have been known to pay her the same attentions for months, and to brush and lick her continually. Different species vary in their instincts, which produces some variation in their domestic proceedings, but the general line of conduct is the same throughout. In some nests several female ants have been known to live together on amicable terms, showing none of the spirit of exclusive rivalry so observable in the queen bee. Of all insects the ants seem to have the most perfect mode of communicating with each other. On this curious subject, the learned entomologists Kirby and Spence thus express themselves: — "The fact being certain that ants impart their ideas to each other, we are next led to inquire by what means this is accomplished. It does not appear that, like the bees, they emit any significative sounds; their language, therefore, must consist of signs or gestures, some of which I shall now detail. In communicating their fear or expressing their anger, they run from one to another in a semicircle, and strike with their head or jaws the trunk or abdomen of the ant to which they mean to give information of any subject of alarm. But those remarkable organs, their antennæ, are the principal instruments of their speech, if it may be so called, supplying the place both of voice and words. When the military ants before alluded to go upon their expeditions, and are out of the formicary, previously to setting off they touch each other on the trunk with their antennæ and forehead: this is the signal for marching; for, as soon as any one has received it, he is immediately in motion. If a hungry ant wants to be fed, it touches with its two antennæ, moving them very rapidly, those of the individual from which it expects its meal. The helpless larvæ, also, of the ants are informed by the same means when they may open their mouths to receive their food. Whether ants, with man and some of the larger animals, experience any thing like attachment to individuals, is not easily ascertained; but that they act as if they felt the full force of the sentiment which we term patriotism, or the love of the community to which they belong, is evident from the whole series of their proceedings. Distress or difficulty falling upon any member of their society generally excites their sympathy, and they do their utmost to relieve it."

The attachment of the neuters is continued to the offspring of the perfect female through the states of ova, larva, and pupa, and even increases at each progressive stage; their greatest cares are lavished on the cocoon, which they may be seen bringing out into the air in fine weather, and carrying back again into the nest when the heat is too great, or on the approach of rain, of which they have an instinctive knowledge. It is the cocoons, also, which are the first objects of their solicitude when the formicary is broken in upon; and although the cocoon is double the size of the neuter itself, yet it bears it away with an agility which shows that the weight is no incumbrance.

The combats between the ants of neighbouring communities are generally caused by the instinctive fondness which the workers have for the cocoons, and which they cannot see without attempting to appropriate it as an object of care and attention. In their battles they fight with fierceness and obstinacy, sometimes carrying off the head of the vanquished upon their antennæ, like an American Indian who bears his enemy's scalp about his neck as a trophy; not that the ant warrior voluntarily carries this troublesome proof of his valour, for he would willingly be rid of such an incumbrance, but this is seldom the case while he lives.

The males and females never fight; the neuters alone attacking or defending. Besides their other weapons, ants are furnished with the power of ejecting an acrid

juice from their abdomen, in sufficient quantity and force to repel any small antagonist.

Huber also gives a most terrific account of the civil wars between ants of the same species, but composing different communities. Nothing can exceed the ferocity or pertinacity of these battles. The infuriate creatures tear each other almost to pieces,—now struggling in single combat, till a third, coming up, puts an end to the affair, by helping to kill or take the enemy prisoner!—now fighting in bodies linked together, and refusing all quarter, till a reinforcement alters the tide of war, and gives victory to one side. But these battles are frequently renewed day by day, the combatants retiring as night approaches, till the rainy season brings the fierce little citizens to reason, and both parties retire to their citadel. It is a curious fact that, though the opposing armies are of one species, each party knows a fellow-lodger even in the wildest part of the action; for Huber states, that if by accident an ant had attacked a friend, caresses immediately succeeded to blows. M. P. Huber states as a fact the startling circumstance of certain species of ants (*F. rufescens*, and *F. sanguinea*, Latr.) procuring slaves which they carry off in predatory excursions while in an infant state. These slaves are of a small black species, and when reared perform the offices which generally devolve upon the neuters or workers in other societies; besides which they have to feed their masters and carry them about the nest. Indeed, so totally dependant are their masters upon these indefatigable little slaves, that the term should rather be reversed; for it appears that these lords of the community may not venture forth from the nest but with permission of the negroes; and M. P. Huber proved, by experiment, that they would die of starvation if not fed by these indispensable servants. There is likewise another species (the *F. cunicularia*, L.), which are forcibly carried off by the rufescent ants; but from their being more courageous than the negro species, the depredators are obliged to go with greater strength of numbers and more precaution. The account which M. Huber gives of these excursions after slaves is highly curious and interesting; the enemy, making use of manœuvres and tactics, and the assailed receiving them with such arrangements, as any but a close observer of insect economy and habits would declare to be impossible but to human intellect. The *F. sanguinea* is not, however, so helpless and utterly dependant on the black ants; but will rouse themselves upon occasion, and protect their slaves, and even transport them to another habitation when changing their residence, which is sometimes the case.

The negro and miner ants, when attacked by the marauding species in their dwelling, make every effort to place the young brood and the newly excluded females out of danger, carrying them to some distant place of security as soon as the alarm is given, and during the combat hundreds are so employed; but when tranquillity is once more restored, they bring back these precious charges, and place them within the walls of the fort, of which they barricade the entrances, and place a strong guard near in case of future attempts. To prove how dependant the rufescent ants are upon their little notable black servants, Huber tells of an experiment he made, by shutting up thirty of them in a glazed box, supplying them with honey in one corner of their prison, and placing with them larvæ and pupæ both of their own species and that of the negro. At first they made some little exertions in regard to the young, carrying them from one place to another, but soon seemed to find this too great an effort; and though food was in the box, most of them died in a few days, rather than help themselves to it. Huber, in commiseration of their wretched condition, then put in a single little negro ant, which actively set to work, making a cell in the earth, into which it collected the larvæ, and feeding the pupæ ready to emerge, as well as the still surviving neuters Huber also mentions other experiments tending to the same end, which perfectly succeeded in showing the vital importance of these slave ants to their masters under various circumstances, and proved that this curious habit depends on something more than the mere blind attachment of the imperfect females for *pupæ*.

Linnæus speaks of the strange fact of "ants milking their cows, the *Aphides*;" and Huber relates many highly interesting particulars in addition. He says, the ants not only suck the sweet juice which is constantly passing through the body of the *Aphides*, but make use of their antennæ during the operation, to produce a ready evacuation, patting the *Aphides* on the sides pretty briskly. They are very jealous of the possession of these their milch cows, sometimes fighting fiercely in their defence, and forming earthen boundaries for their detention. The British species of ant (*Formica flava*, Gould) is especially fond of collecting herds of the *Aphis radicum* in its hemispherical formicary, tending the eggs as it would those of its own brood. This yellow ant exceeds all the other species of Aphis-loving *Formica* in the great number of its herds.

It appears, from observations made both by Gould and Huber, that when a nest becomes overpopulated, or from some other reason, emigrations take place, which are conducted in a very interesting and singular manner. A few having apparently made up their minds on the subject, endeavour, by the usual signs, to induce others to accompany them to the spot chosen for the new encampment; and having so far succeeded, carry the newly-persuaded recruit upon their mandibles thither, who in his turn goes back with his conductor to the old nest, and engages a fellow-citizen to accompany him also, and thus by degrees the whole congregation emigrate. This emigration does not, in all instances, proceed by dint of persuasion; for the recruiting ant will, without warning, sometimes seize upon another, and carry it off suddenly to the new site: which rough proceeding does not, however, prevent the ant so removed in joining in the attempt to raise more recruits; for it returns, like the others, and fetches a companion. The turf ants (*F. cæspitum*, L.), upon these occasions, carry their fellow emigrants in an uncoiled form, with the head downwards. These observations chiefly apply to the great hill ant (*F. rufa*), though several other species migrate. They will, in case the new settlement is at a considerable distance, form temporary colonies by the way, all, however, uniting at last in one principal formicary.

Ants work during the night as well as by day.

Our native ants usually make their first appearance in March, and continue in activity till the middle or end of October. They are fond of basking and sporting in the sun; and their antics, at these times, are described by the best observers as exceedingly amusing, some appearing to wrestle, and others actually carrying each other on their back in the most playful manner. They are not torpid during the whole winter, but are, in genial and mild days, sometimes to be seen in full activity. Extreme cold causes them to cluster together in compact bodies, as if by this means to preserve a sufficient quantity of animal heat to allow of their occasional return to the labours of life. That ants will attack and kill, for food, insects and animals infinitely larger than themselves, is very well known: their strength is prodigious compared with their size. Mr. Kirby says, "I have seen an ant dragging a wild bee many times bigger than itself."

The bite of some foreign ants is very severe. Sir Joseph Banks observed a green species in New South Wales which inflicted a wound scarcely less painful than that of a bee. One, called the fire ant, is so called from its bite resembling the pain occasioned by a spark of fire. Some ants in Ceylon produce great anguish from their bite. Those species usually found in Great Britain may almost be called harmless in this respect.

There is a species in Cayenne (*Formica bispinosa*) which collects from the bombax and silk cotton tree a sort of lint which the natives value much as a styptic in cases of hæmorrhage; but though this species benefits man, there are several whose ravages have sometimes more than counterbalanced the good produced by these insects. Within the last century, what might truly be called a plague of ants appeared at one period in the island of Granada, in such hosts as to put a stop to the cultivation of the sugar cane. The destruction of this plant is not caused by the ants devouring it, but by their constructing their nest under its roots. At the time of this irruption, their numbers were only to be compared with sand strewed over every place and thing. They descended from the hills, and covered the plantations; and did not confine their attacks to plants, but rats, mice, and even birds, when alighting on the ground, fell a prey to them. Streams of water only opposed their frightful progress for a moment, masses of them rushing, or being impelled by the hosts behind, into the water, and only forming by their carcasses a raft or bank for the rest to pass upon. Fire was tried in vain as a barrier to their progress; such infinite swarms rushed into the blaze as to extinguish it. A reward of 20,000*l*. was offered to whoever should discover an effectual method of destroying them, but in vain. The standing crops of sugar cane were burnt down, and the earth dug up; but no human means was found effective. At length, in the year 1780, they were annihilated by the torrents of rain which accompanied an awful hurricane, which was most fatal in its effects to the other West India islands. But it is only fair to state, after such an account of devastation, that such an occurrence is exceedingly rare; and that these all-devouring creatures, besides being admirable in their household economy and laws, benefit us by removing and destroying multitudes of tormenting insects and reptiles, and in their turn serve as food to thousands of other animals.

Several species of Mammalia, in foreign countries, are expressly organized for restraining the undue increase of this genus of insect (see *Myrmacophaga*), having claws of prodigious strength for making a breach into the strong walls of the formicaries of the exotic ants, and a long glutinous tongue for sweeping off thousands of the disturbed community. In England, the habitations of

the various species of ants are less conspicuous, but not less curious, than the formicaries of tropical countries. They are thus described by Kirby and Spence:—

"The nest of the large red ants (*F. rufa*, L.), which are common in woods, at the first aspect seems a very confused mass. Exteriorly it is a conical mount, composed of pieces of straw, fragments of wood, little stones, leaves, grains; in short, of any portable materials within their reach; but, however rude its outward appearance, and the articles of which it consists, interiorly it presents an arrangement admirably calculated at once for a protection against the excessive heat of the sun, and yet to retain a due proportion of genial warmth. It is wholly composed of numerous small apartments of different sizes, communicating with each other by means of galleries, and arranged in separate stories, some very deep in the earth, others a considerable height above it; the former for the reception of the young in cold weather and at night, the latter adapted to their use in the daytime. In forming these, the ants mix the earth excavated from the bottom of the nest with the other materials of which the mount consists, and thus give solidity to the whole. Besides the avenues which join the apartments together, other galleries, varying in dimensions, communicate with the outside of the nest at the top of the mount. These open doors would seem ill calculated for precluding the admission of wet or nocturnal enemies; but the ants alter their dimensions continually, according to circumstances; and they wholly close them at night, when all gradually retire to the interior, and a few sentinels only are left to guard the gates. On rainy days, too, they keep them shut; and when the sky is cloudy open them partially.

"The habitations of these ants are much larger than those of any other species in this country, and sometimes as big as a small haycock; but they are mere molehills when compared with the enormous mounds which other species, apparently of the same family, but much larger, construct in warmer climates. Malouet states, that in the forests of Guiana he once saw ant-hills which, though his companion would not suffer him to approach nearer than forty paces for fear of his being devoured, seemed to him to be fifteen or twenty feet high, and thirty or forty feet in diameter at the base, assuming the form of a pyramid, truncated at one third of its height; and Stedman, when in Surinam, once passed ant-hills six feet high, and at least one hundred feet in circumference.

"The nest of *Formica brunnea*, Latr., is composed wholly of earth, and consists of a great number of stories, sometimes not fewer than forty,—twenty below the level of the soil, and as many above; which last, following the slope of the ant-hill, are concentric. Each story, separately examined, exhibits cavities in the shape of saloons, narrower apartments, and long galleries, which preserve the communication between both. The arched roofs of the most spacious rooms are supported by very thin walls, or occasionally by small pillars and true buttresses; some having only one entrance from above, others a second, communicating with the lower story. The main galleries, of which in some places several meet in one large saloon, communicate with other subterranean passages, which are often carried to the distance of several feet from the hill. These insects work chiefly after sunset. In building their nest, they employ soft clay only, scraped from its bottom when sufficiently moistened by a shower, which, far from injuring, consolidates and strengthens their architecture. Different labourers convey small masses of this ductile material between their mandibles; and with the same instruments they spread and mould it to their will, the antennæ accompanying every movement. They render all firm by pressing the surface lightly with their fore feet; and, however numerous the masses of clay composing these walls, and though connected by no glutinous material, they appear, when finished, one single layer, well united, consolidated, and smoothed. Having traced the plan of their structure, by placing here and there the foundations of the pillars and partition walls, they add successively new portions; and when the walls of a gallery or apartment, which are half a line thick, are elevated about half an inch in height, they join them by springing a flattish arch or roof from one side to the other. Nothing can be a more interesting spectacle than one of these cities while building. In one place, vertical walls form the outline, which communicate with different corridors by openings made in the masonry; in another, we see a true saloon, whose vaults are supported by numerous pillars; and further on are the cross ways or squares where several streets meet, and whose roofs, though often more than two inches across, the ants are under no difficulty in constructing, beginning the sides of the arch in the angle formed by two walls, and extending them by successive layers of clay till they meet; while crowds of masons arrive from all parts with their particle of mortar, and work with a regularity, harmony, and activity which can never enough be admired. So assiduous are they in their operations, that they will complete a story, with all its saloons, vaulted roofs, partitions, and galleries, in seven or eight hours. If they begin a story, and, for want of moisture, are unable to finish it, they pull down again all the crumbling apartments that are not covered in.

"Another species of ants (*F. fusca*, L.) are also masons. The societies of *F. fuliginosa*, Latr., make their habitations in the trunks of old oaks or willow trees, gnawing the wood into numberless stories, more or less horizontal. Two other tribes of carpenter ants (*F. æthiops*, and *F. flava*, Latr.) use saw-dust in forming their buildings. Some ants form their nests of the leaves of trees. One of these was observed by Sir Joseph Banks in New South Wales, which was formed by glueing together several leaves as large as a hand. To keep these leaves in a proper position, thousands of ants united their strength; and if driven away, the leaves spring back with great violence."

FO'RMIC ACID. A sour liquor which ants eject when irritated, and which was formerly obtained by bruising the insects and distilling them, mixed with water: a peculiar volatile acid passed over. It has been ascertained by Döbereiner, that an analogous acid may be artificially obtained by distilling, from a capacious retort, a mixture of 2 parts of tartaric acid, 3 of peroxide of manganese, and 3 of sulphuric acid diluted with 5 of water. The tartaric acid acquires oxygen from the oxide of manganese, and is resolved into water, carbonic acid, and formic acid. From the analysis by Berzelius of formiate of lead, it appears that formic acid is a compound of 2 atoms of carbon, 3 of oxygen, and 1 of hydrogen; or of 2 atoms of carbonic oxide and 1 of water.

FORMICA'TION. (Lat. formica, *an ant.*) The creeping sensation upon the skin, resembling the crawling of ants over different parts of the body.

FO'RMULA. In Algebra, the expression of a theorem or general rule for the solution of some problem. Thus the area of a triangle is expressed in terms of its three sides, a, b, c, and the semiperimeter, s, by the formula $\sqrt{s(s-a)(s-b)(s-c)}$.

FORMULA, or FORMULARY, in Medicine, &c., signifies a prescription.

FORNES. A term occasionally applied by medical writers to the infectious causes of diseases.

FORNIX. (Lat.) An arch. In Anatomy, this term is applied to a part of the *corpus callosum* of the brain, which, when viewed in a particular direction, somewhat resembles the shape of a Gothic arch. It is the medullary body, composed of two anterior and two posterior *crura*, situated at bottom and inside of the lateral ventricle, over the third ventricle and below the *septum lucidum*. *See* BRAIN.

FO'RSTERITE. A mineral named after Mr. Forster; it forms brilliant and small crystals, colourless and translucent, and is found at Vesuvius, accompanied by pyroxene. It contains silica and magnesia, but has not been carefully analyzed.

FORT. A castle or small fortress; a place of inconsiderable extent, fortified by nature or art. *Field-fort*, or fortlet, is a small fort, principally constructed for the defence of a camp, or for defending a *pass* or *post*.

FO'RTE. (Ital.) In Music, a direction to the performer to execute the part loudly to which the word is affixed. It is indicated by the single letter F. If two F F's, thus, are used, the part is to be played or performed *fortissimo*, very loud.

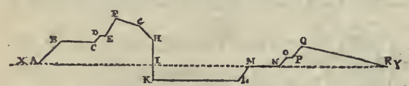
FO'RTIFICATION, also called *Military Architecture*, is the art of constructing such works of defence as may enable a comparatively small number of men to maintain possession of a city or place against the assaults of a superior force.

The nature of constructions necessary for defence will be determined by the means of aggression. In early ages, when the sling and the bow formed the principal weapons of offence, men considered themselves sufficiently defended by a single wall or a bank of earth, from behind which they could discharge their missiles against their assailants. In progress of time projecting towers were added, which served the double purpose of increasing the front of the besieged, and of enabling them to attack in flank the besiegers when approaching to scale the wall. The invention of the battering ram rendered no other change necessary than that of increasing the thickness and strength of the wall. To aid the means of defence, projecting galleries were constructed at the summit of the wall and round the towers, through the pierced floors of which stones and other missiles were showered down on the heads of the assailants. These galleries were called *machicoulis* or *massecoulis*, from the French *couler des masses;* because they served the purpose of enabling the besieged to let fall heavy masses, to which cords were attached, in order that they might be drawn up again and let fall anew when the enemy returned to sap. Apertures or loop-holes for the discharge of arrows and javelins were made in the battlements, or

pierced in the walls; and the defensive means were completed by surrounding the whole place with a deep moat or ditch. But the invention of gunpowder rendered it necessary to adopt an entirely different system of defence. Walls of masonry, however thick, can withstand for but a short time the assault of heavy artillery; hence those successive circumvallations and constructions of earth which constitute the defences of a modern fortress.

Happily for Great Britain, whose insular situation has exempted her from foreign invasion, her internal dissensions have neither been so frequent nor so protracted as to render the art of constructing permanent fortifications of much national importance. It has been on the continent of Europe, where war has flourished in greater vigour, that the art has been created and chiefly cultivated. A modern fortification consists of a great number of parts, to which, for the purposes of description, it is necessary to give distinct names; and it would naturally happen that those who first contrived the particular forms of the different parts would designate them by names drawn from their own language. These appellations, chiefly of French, but occasionally of Italian origin, have been transferred into our language by the ignorance of translators, and carefully retained through the pedantry of our military engineers; so that all our works, without exception, which treat of fortification, are obscured by a mass of barbarous jargon, through which it is difficult to catch a glimpse of the few simple principles which determine the forms of all defensive constructions.

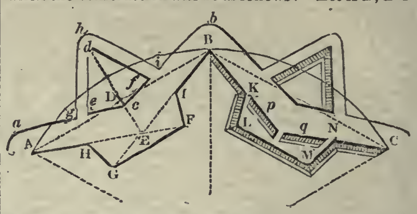
Modern fortifications, though differing in some subordinate details, which differences are dignified by the name of *systems*, closely resemble one another in all their essential parts. In order to explain their structure, it will be convenient to consider them first without reference to their form, or the position of the ground lines in respect of each other, but merely as defences against an army with artillery advancing directly in front. The annexed figure represents a vertical section of a regular



fortification on the ground line X Y, the place to be defended being supposed between X and A. The mass of earth A B C D E F G H forms the rampart with its parapet. A B is the interior slope of the rampart; B C is the *terre-plein* of the rampart, having a breadth of about 40 feet, on which the troops and cannon are placed; D E is called the *banquette*, or step, on which the soldiers mount to fire over the parapet; E F G is the *parapet*, of a height (about 7 feet) sufficient to protect the men and guns on the terre-plein, and sloped in the direction F G towards M, the opposite edge of the ditch, so that a man approaching there may be seen and fired at; G H is the exterior slope of the parapet; H I is the *revetment* or wall of masonry supporting the rampart, and strengthened by buttresses placed at small intervals behind it. This must be of sufficient height to prevent its being easily scaled; but yet must not rise higher than the edge of the exterior work at Q, in order that it may not be seen and breached by distant batteries. The exterior front of the rampart, covered with the revetment H K, is called the *escarp;* I K L M is the ditch, the dimensions of which will be determined by the nature of the ground, but must be such, in general, that its excavation or *deblai* must produce sufficient earth or *remblai* to form the rampart; the opposite side of the ditch L M is the *counterscarp*, also supported by a revetment of masonry; M N is the *covered way*, a space about 10 yards in breadth, having a *banquette* N O P, and protected by a parapet P Q, the superior slope of which, Q R, is called the *glacis*. The use of the covered way is to allow troops to be drawn up, unseen by the besiegers, for the purpose of making sorties; it also enables the garrison to keep up a closer fire on the approaches of the enemy, and its parapet forms a strong protection to the revetment of the rampart.

It is easy to see that the strength of a place will be increased by a succession of such works, so that when the besieged are driven from one they may retire to the next behind it. Sometimes there are three ditches with intermediate works, or rather works raised within the ditch itself, similar to the rampart, though of a less height, in order that the guns on the rampart may range above them. A work of this sort, between the inner and the main ditch, is called a *tenaille;* that between the main ditch and the outer ditch is called a *ravelin*. All works outside the ditch are called *outworks*.

Before proceeding to construct a fortification, it is necessary to lay down a *plan*. This will differ in some respects according to the system adopted; but the following description, which properly belongs to Vauban's First System, will explain the general method: — When the work is regular, the sides are all equal, and therefore the general form will be that of a polygon inscribed in a circle. The first thing to be done is to determine on the number of sides. We shall suppose them to be six, and the radius of the circumscribing circle to be 360 yards, when the construction will be as follows: — Let A B, B C



be two sides of a hexagon inscribed in a circle; each of these lines will be equal to the radius, or 360 yards. Bisect A B in D; draw the perpendicular D E, on which set off D E, equal to one-sixth of A B, or 60 yards; draw the lines A E F and B E G, in which take A H and B I, each equal to 100 yards, or five-ninths of A D; make H F and I G each equal to the distance H I; then the line A H G F I B is the principal outline of the front, and by making the same construction on each of the sides of the hexagon, we obtain the principal outline of the whole fortification, or that by which the first figure of the work is defined.

The part F I B K L is called the *bastion*, B I and B K are the *faces* of the bastion; I F and K L are its *flanks;* F L is the *gorge;* G F is the *curtain;* A F and B G are the *lines of defence;* B is the *flanked angle;* I and K are the *angles of the shoulder;* G, F, L, and M the *angles of the flank*. From the points A and B as centres, and a radius of 40 yards, describe circular arcs; if lines be drawn from the opposite angles of the shoulder H I to touch those arcs, the parts of those lines *a c*, *b c*, together with the arcs, will represent the *counterscarp* of the ditch. The curtain is defended by a *ravelin*, which is constructed thus: — From *c*, the re-entering angle of the counterscarp, set off, on the perpendicular D E, a line *c d*, equal to 110 yards, and from *d* draw *d e*, *d f*, in the directions of H and I, to meet the counterscarp; then *d e* and *d f* are the *faces* of the ravelin, and *c e* and *c f* its *semigorges*. The counterscarp *g h i* of the ditch of the ravelin is parallel to its faces, and rounded off at *h*. Stairs, called *pas-de-souris*, are constructed to facilitate the descent from the ravelin to the ditch. Besides the ravelin, there is usually another appendage to the bastion and curtain. This is the *tenaille*, represented in the figure by the parts *p q* made in the direction of the lines of defence; but it has sometimes other forms. The tenaille is made in the ditch before the curtain, with passages between the ends and the flanks of the bastion. It is a low work, having its parapet only about 3 feet higher than the level ground of the ravelin, and its use is to defend the bottom of the ditch by a grazing fire.

Such are the works which form the envelop of the place fortified; but various other constructions are in most cases added, according to the nature of the ground and other circumstances, for the purpose of protecting or strengthening such parts as are most exposed, or of interrupting the works of the besiegers. These additional constructions are either internal or external. Among the former are *retrenchments* of various kinds, either constructed at the same time with the principal works or thrown up during the siege. They are made behind the ramparts, or the bastions most exposed to attack, their use being to enable the garrison to continue the defence from behind a fresh obstacle when a rampart or bastion has been breached. When a hill or rising ground overlooks any of the works, a *cavalier* is raised, about ten or twelve feet higher than the rest of the works. This is commonly placed within the bastion when it has the same form, but sometimes on the middle of the curtain when its form is semicircular. Of the exterior works one of the most important is the *counterguard*, constructed to cover some of the principal parts, as the bastion or the cavalier, in such a manner that without obstructing their fire it prevents them from being breached till itself is taken. The counterguard is constructed parallel with the faces of the work it is destined to cover; and it must be lower than the principal work, though of a sufficient height to screen its revetment.

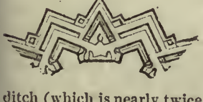
A *horn-work*, represented in the annexed figure, is composed of two branches, and a front composed of two half bastions and a curtain, resembling a front of the body of

the place. It is here represented as made before the curtain, but it may be also constructed before a bastion. A *crown-work* is of the same nature as a horn-work, but larger, and having two fronts, which give it somewhat the appearance of a crown. Horn-works and crown-works are constructed where a large spot of ground lies beyond the fortification which might be advantageous to an enemy, or to cover a gate or entrance into a town. *Lunettes, a a*, are placed on both sides of the ravelin, and are constructed on lines bisecting the faces of the ravelin at right angles. A *bonnet, b*, is a work covering the salient angle of the ravelin. *Tenaillons* are similar in construction to lunettes, but having one of their faces formed on lines which are the production of the faces of the ravelin, instead of bisecting those faces. The application of all these and other works of a similar description depends on the nature of the localities; and it must be left to the judgment of the engineer to determine in each particular case which is best adapted to the ground.

We have already alluded to the use and importance of the covered way. In order to increase its strength *traverses*, or portions of parapet, are thrown across it, which screen it from an enfilading fire, and enable the defenders to dispute its possession foot by foot. *Places of arms*, or places for assembling troops, and protected by traverses and *redoubts*, are also formed on it at the re-entering and salient angles of the counterscarp. The redoubts serve not only as a place of retreat, but facilitate the making of sorties upon the enemy's lodgments.

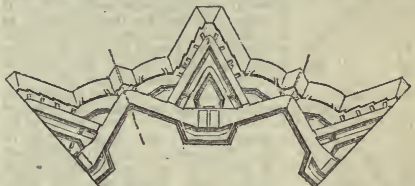
The descriptions given above belong more especially to that method of fortification which, in the military schools, is denominated Vauban's first system. Marshal Vauban served in the wars of Louis XIV., and in the course of his life directed the construction of thirty-three new fortresses, and the improvement of three hundred others. From the different constructions observed in these works have been compiled his *three* systems; which, however, in a general view of the subject, may be considered as only differing in points of detail, or in a greater or less degree of complication. In his second system, represented in the annexed figure, he separated the bastions from the body of the place by a ditch about 40 feet wide, in order that the besieger, after the breach and capture of the bastions, might be compelled to renew his operations against the *enceinte* or body of the place. The angles of the polygon are crowned by pentagonal towers of masonry, called *tower bastions*, to which, in fact, the regular bastions only form counterguards. It was from a desire to take advantage of these tower bastions, which he found already existing at Landau when called upon to fortify that place, that he was led to adopt the system in question. Vauban's third system does not differ in any material respect from the second. He increased the size of the ravelin, and gave it a redoubt. The tower bastions were likewise made larger, and the curtain which united them was broken inwards, so as to form two small flanks underneath; while casements for cannon were constructed, to co-operate with those of the tower bastions in the defence of the ditch.

Cochorn's System.—Contemporary with Vauban was the Baron de Coehorn, director-general of the fortifications of the United Provinces of Holland. This celebrated engineer is also the author of three different systems, though the third has never been constructed. His methods are only applicable in low swampy countries, like Holland; and the object which he kept principally in view was to throw such obstacles in the way of a besieging force that the place could only be approached with great difficulty and hazard. This he sought to accomplish by covering and flanking his works more effectually than had previously been done, and by depriving the assailant of the room necessary for erecting his batteries. An idea of his methods may be formed from the annexed figure, which represents his first system. It is constructed on a hexagon; the second was on a heptagon, and the third on an octagon. And it may be remarked of his systems in general, that they differ from Vauban's principally in the greater width of the ditch (which is nearly twice as wide as in Vauban's systems) and the narrow space between the flanks. Coehorn's principles have been adopted in the construction of the fortresses of Nimeguen, Breda, Manheim, Namur, and Bergen-op-zoom.



Cormontaigne's System.—The methods of Vauban were improved in many essential respects by Cormontaigne, a French officer of engineers, who died in 1750. In the system which he adopted, and which is here represented, the faces of the bastion are made longer than in Vauban's methods, and the flanks are placed at right angles with the faces of the opposite bastions. The enlargement of the bastion renders it capable of containing interior retrenchments; and the flanks, though shortened, are better covered. His ravelins are also constructed on a larger base, and contain a larger redoubt, from which the besiegers can keep up a reverse fire on breaches made in the collateral bastions; so that the assault upon the latter becomes impracticable until the ravelin and its redoubt are both captured. The communication round the extremities of the traverses of the covered way are arranged in a zig-zag line; so that the passage round the extremity of one traverse is defended by the fire of another in its rear, and the advance of the assailants along the covered way thereby checked. In general, Cormontaigne's system possesses greater defensive properties, and is more economical of materials.

Modern System.—The annexed figure represents what is called the modern system: it varies but little from that of Cormontaigne. The ravelin is made to cover the shoulder of the bastion more effectually by a greater projection, and its faces are retrenched by *coupures* or cuts through the rampart, perpendicular to the faces of the bastion, which prevent the enemy from taking the redoubt in the re-entering place of arms without first possessing himself of the redoubt in the ravelin.

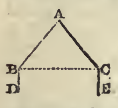


All the systems above enumerated, however they may differ in details, agree in their principal features, and present the same general outline. They may be all included under the name of the bastion system. Some engineers, however, among the most celebrated of whom are Montalembert and Carnot, have pointed out defects which appear to be inherent in the system, and proposed to give the polygon a different form. By suppressing the curtain and the tenaille, and producing the faces of the bastions inward, a line of rampart would be formed presenting simply a succession of salient and re-entering angles. According to this plan, the defence is made to depend on the number of reverse fires that can be maintained from casemated (*i.e.* bomb-proof) batteries; but as the plan has never been practically carried into effect, it is unnecessary to enter into particulars. In the present state of the military art, a fortress can be regarded as nothing more than a means of stemming for a time the torrent of an invading force. Such is the superiority of the means of attack over those of defence, that however strong the works may be, and however skilfully disposed, their reduction, when assailed by adequate means, is, generally speaking, a matter of absolute certainty. The besieging army, sheltered by its trenches from the missiles of the garrison, advances in zig-zag lines parallel to the faces of the ramparts, till it passes over or circumvents all the exterior defences of the place, and arrives at the main wall, where a breach has been made by batteries erected for the purpose. To this covered mode of attack, supported by the ricochet batteries, by which the defenders are driven from the ramparts and the guns dismounted, it is perhaps impossible to offer any effectual resistance. Indeed, such is the perfection to which the art of attack has been reduced, that even the length of time which any fortress will be able to hold out against an enemy provided with the proper train of sappers and miners, and the implements necessary for carrying on their operations, may be computed with the greatest precision.

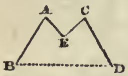
Field Fortification.—Field Fortification is the art of constructing all kinds of temporary works for assisting the operations of an army in the field, and enabling it to maintain a position against a superior force. In the disposition and construction of such works, the engineer must have regard to the nature of the locality, and endeavour to turn to the best account all its natural advantages, as well as the buildings, enclosures, &c., which may be found on it; and there is no part of his art in which talent and skill are so requisite, or in which he must rely so exclusively on the resources of his own judgment. On account of the endless varieties and accidents of the ground on which he has to act, the observance of fixed rules is indeed impracticable: nevertheless

there are certain general maxims which apply to the construction of fortifications of all kinds, whether temporary or permanent, and which must be observed in all his operations. For example, works constructed to flank others, must not be at so great a distance as to be beyond the effective range of musketry: the angles of defence should be nearly right angles, and the salient angles as obtuse as possible. The general nature of defensive works is also the same in all cases, namely, a ditch and a parapet; though, as the pick-axe and the spade are the only implements which an army in the field can carry about with it, the depth and width of the ditch and the height of the parapet are in field-works necessarily limited to what can be effected by these simple means.

Field-works are usually divided into three classes:—1. Works open at the gorge; 2. Works enclosed all round; and 3. Lines either continued or with intervals. To the first class belong *redans*, single and double, *tenailled heads*, and *bastioned heads;* to the second, *redoubts*, *star forts*, and *bastioned forts;* and to the third, lines of various kinds for defending a position. The *redan* is the simplest of all works, consisting merely of two lines, A B and A C, forming an angle with each other. It is only employed for such purposes as defending the avenues of a village, bridge, or defile. The length given it is usually about 50 yards. When the redan is thrown out in front of other works it is called a *fleche*, or arrow. Lunettes are also applied for similar purposes, and are formed by adding two parallel faces, B D and C E, to the redan, at the extremities of its open flanks.



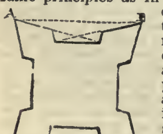
The *double redan*, or *bonnet de prêtre*, consists of two faces, A B and C D; and two flanks, A E and C E, usually shorter than the faces, and affording a reciprocal defence to each other. The re-entering angle at E should be a right angle; if it is less, the two flanks are in danger of being struck by each other's fire; and if it is much greater than a right angle, the defence will be weakened; for it is found by experience that soldiers placed behind a screen invariably fire straight before them, or at right angles to the screen. When a greater extent of front is to be fortified, the lines are disposed in the form of bastions or tenailles, and thence called *bastioned heads* and *tenailled heads*.



Redoubts are works closed on all sides, of a polygonal or quadrilateral figure, and usually square. An opening is left in one of the sides, for communication with the exterior, and a traverse is thrown up within for protection. As the work is without flanks, the ditches are left without defence. The angles are sometimes rounded, or cut off, in order that a fire may be maintained on an assailant advancing in the direction of the diagonal.

Star forts are enclosed works constructed upon an equilateral triangle or a square. In the former case they have six points, in the latter eight. When constructed on a square each of the sides (which may be about 90 yards long) is divided into three equal parts, and on the middle part an equilateral triangle is constructed, which gives the trace of the figure. The object of this work is to remedy the defects of the redoubt by flanking the angles of the square; but as a considerable space is consumed by the re-entering angles, it scarcely admits of sufficient troops and artillery being placed in it for its defence.

Bastioned forts are constructed in the field on the same principles as in permanent works; but are only constructed on the square or pentagon. The distance A B, or exterior side of the polygon, should not exceed the range of musketry, or about 200 yards. They are employed only in fortifying important positions, and require accordingly to be constructed in a more solid manner than other works of a temporary nature.



The last class of field-works comprehends *lines* of various descriptions. *Continued lines* are constructed to enclose a front, or connect principal works with one another by a continued parapet. They are constructed, according to circumstances, with redans, tenailles, or bastions, placed at certain intervals, seldom exceeding 180 yards. From the descriptions given above, the different forms of the *redan line*, *tenaille line*, and *bastion line* will be readily conceived. Sometimes they are formed of a succession of faces and flanks at right angles. In this case they are called *lines-en-cremaillères*. The flanks are about a fourth of the length of the faces, and afford a defence to the ditches. Lines with intervals consist of isolated works, as redans or redoubts, placed at distances which should not exceed 200 yards. and so as to afford one another a mutual defence.

Besides the works now enumerated, various expedients are resorted to in order to prevent, or at least to render more difficult, the appproaches of an enemy. Among these are *palisades*, *abatis*, *trous-de-coup*, *chevaux-de-frize*, *crows' feet*, &c.

The principal authors on Fortification are Errard, Stevinus, Antoine de Ville, Compte de Pagan, Coehorn, Vauban, Mallet, Belidor, Blondel, Montalembert, Bisset, Bousmard, Carnot, Mouzé, &c. For a practical treatise the reader may be referred to the article "Fortification" in the *Ency. Metropolitana.*

FORTRESS. Any fortified place. (See the preceding article.)

FORTIN, FORTRET. A sconce or small fort.

FORTU'NA. In Mythology, the goddess who presided over the destinies of mankind, and generally speaking over all the events of life. She was represented as blind, with winged feet, and resting on a wheel. This goddess was not known in the more ancient systems of the Greek theogony: all the guidance of human affairs, for instance, is intrusted by Homer to Destiny; but in Italy, and chiefly at Rome, Actium, and Præneste, her worship was most assiduously cultivated.

FO'RUM. (Lat.) In Ancient Architecture, a public market; also a place where the common courts were kept, and matters of judgment pleaded. The fora of the Romans were large open squares surrounded by porticoes; parts of which answered for market-places, other parts for public meetings of the inhabitants, and other parts for courts of justice. The forum was also occasionally used for shows of gladiators. There were in Rome seventeen; of these fourteen were for the sale of goods, provisions, and merchandize, and called Fora Venalia; the other three were for civil and judicial proceedings, and called Fora Civilia et Judicialia: of the latter sort was the forum of Trajan, of which the Trajan column formed the principal ornament. The forum of the Romans was identical with the ἀγορὰ of the Greeks.

FO'SSA (Lat. fossa, *a trench*), in Zoology, is applied to certain depressions on the external surface; generally the seat of cutaneous glands, as the lachrymal fossa in deer and antelopes, the *jugular fossa*, *inguinal fossa*, &c.

FO'SSA OVA'LIS. A depression in the right auricle of the heart, which in the fœtal state opened into the left auricle, forming the *foramen ovale.*

FOSSE (Fr.), in Fortification, is the moat or ditch surrounding the rampart. *See* FORTIFICATION.

FO'SSIL. (Lat. fodio, *I dig.*) Literally, any thing dug out of the earth. The term is now chiefly confined to organic remains.

FO'SSIL FARINA. A soft carbonate of lime.

FOSSO'RES. (Lat. fodio, *I dig.*) An extensive group of Aculeate Hymenopterous insects, most of the species of which are organized for excavating cells in earth or wood, in which they bury other insects in a wounded and feeble state, and at the same time deposit their eggs; so that the larvæ, when hatched, find a store of food prepared for their sustenance. The Fossorial Hymenoptera are solitary in their habits; and some species, which have not the requisite structure of the legs for burrowing, are parasitic, and, like the cuckoo among birds, lay their eggs in the nests of other species, at whose expense the young are reared.

FOSSO'RIAL. (Lat. fodio, *I dig.*) In Zoology, animals which dig their retreats and seek their food in the earth are so called. The locomotive extremities, which are organized for burrowing, as those of the mole, or mole-cricket, are called "pedes fossorii."

FO'SSULATE. (Lat. fossa, *a trench.*) When a surface presents one or more somewhat long and narrow depressions.

FO'THER, or FODDER, A SAIL. This is thrumming a sail; and covering it with loose stuff, and then passing it under the bottom of a ship that has sprung a leak or been aground, the pressure of the water forces the sail against the bottom, and partly stops the leak.

FOUGASS. In Fortification, a small mine, from 6 to 8 feet under ground. It is derived from the Lat. *focata.*

FOUL. The term applied to the wind when contrary; also to the bottom when uneven and rocky. *See* ANCHOR, FALL, HAWSE.

FOUNDA'TION. (Fr. fondation.) In Architecture, the lower part of a wall, on which the insistent wall is raised, and always of much greater thickness than such insistent wall. A practice has lately been introduced in this country of laying foundations (if not in water) on a bed of what is called *concrete*, which is a mixture of rough small stones or large gravel stones with sand and stone, lime and water, with just enough of the lime to act as a cementitious medium, with the best effect. *See* CONCRETE.

FOUNDA'TIONS. (Lat. fundo, *I institute.*) In Political Economy, the generic name given to institutions established and endowed by individuals, associations, or

the public, for the promotion of what is believed to be at the time when the foundation is made some useful or benevolent purpose. In most old-settled and rich countries there are foundations for a vast variety of objects. During the Middle Ages, it was very common to bequeath property for the foundation of monastic institutions and scholastic establishments. The two great universities of Oxford and Cambridge are noble examples of the last species of foundations; and by far the greater number of the grammar and free schools in most parts of England, and indeed of Europe, owe their origin to the same source. A great deal of property has also been bequeathed by benevolent individuals in this and other countries for the erection and endowment of hospitals, or foundations, of various descriptions, for the relief and assistance of the poor; and not unfrequently also property is appropriated, or a foundation instituted, for the amusement and recreation of the public.

But notwithstanding the large amount of property that has been appropriated in most countries to the establishment of foundations, and their extreme importance in a public point of view, it may appear rather singular that the principles and conditions on which they should be established are far from being well ascertained. No one can doubt that it is highly expedient to allow individuals or associations to institute foundations or to bequeath property for the promotion of beneficial public purposes. But, admitting this, the knotty question arises, how far should the legislature go in authorizing private parties to lay down the conditions under which the property so bequeathed, or the foundation, is to be administered. If, on the one hand, government interference be carried too far, the institution of foundations will be discouraged; and if, on the other hand, government do not interfere at all, the folly or the presumption of individuals will be allowed to legislate for all future ages; and a large amount of property may be appropriated for the support of institutions, which, though once believed to be beneficial, experience may prove to be disadvantageous. The regulation of foundations is therefore a matter of at least as much difficulty as importance, and involves a great variety of considerations. It is impossible, perhaps, to lay down any principles with respect to it that should apply in all cases; but some leading positions may notwithstanding be established, that should always be kept in view and referred to. We shall endeavour to state some of these in our articles on PROPERTY (RIGHT OF), WILLS AND TESTAMENTS, UNIVERSITIES, &c., to which we beg to refer.

FOU'NDING, or FOUNDRY. The building in which various metals are cast into moulds or shapes. Such of the details of the processes carried on in the respective metal foundries as are consistent with the plan of this work, will be found under the heads of the metals to which they refer. The furnaces used in fusing and founding metals are variously constructed, according to the nature of the metal and the quantity to be operated upon; and frequently two or more furnaces of different constructions are employed in the same foundry. The wind furnace, blast furnace, and reverberatory furnace, are the forms which are most generally employed. The wind furnace is either square or circular, and varies in dimensions, according to the size of the crucibles which it is intended to contain, and which are placed upon proper supports, resting generally upon the bars or grating of the furnace. It has three apertures; one above, for the purpose of introducing the crucible and fuel, and which is usually closed by a fire tile or brick; another below, for the purpose of admitting the air, so as to pass through the grate and fuel, and up the chimney; and the third communicating with the chimney, which should be lofty and supplied with a damper, for the purpose of regulating the draught of air through the fireplace, and consequently also the heat produced.

The blast furnace differs from the preceding in having no grating, and in the air being supplied by a bellows or blowing machine. The construction of these furnaces is much varied, according to circumstances; but the largest and most perfect are those employed in the iron works.

The reverberatory furnace is so constructed, that the flame and hot air from the fireplace are directed into a separate cavity intermediate between it and the chimney: in this cavity, commonly called the *hearth*, the materials to be fused are placed; and there is an aperture connected with it by which the fused metal is suffered to run out, or through which it may be removed in ladles for the purpose of supplying the moulds.

The materials of which the *moulds* are formed are very various. In some cases, as in stereotype founding, they consist of plaster of Paris; in bronze works for figures and statues, they are made of a mixture of plaster of Paris, sand, and brick-dust, and require the utmost skill and care in their preparation. Iron is usually cast in sand; brass and other metals in clay; and very frequently the moulds are made of cast iron.

FOU'NDLING HOSPITALS. In those ancient nations with the details of whose social life we are acquainted, the practice of exposing new-born infants seems to have been, as it is at this day in China, a species of legitimate infanticide. Neither Plato nor Aristotle, nor in general any political writers of antiquity, condemn it; they merely profess to lay down rules for the preservation of the healthier and stronger, at the expense of the more weakly. Among the Greeks, a more tender mother chose the market-place, or some temple, for the exposure of her child, in order to have the chance of some charitable hand succouring it: if its death was desired, it was abandoned in solitary places; and their dramas and romances are full of narratives in which this custom forms the foundation of the interest. Thebes, in republican Greece, is the only state in which the exposure of children is known to have been forbidden by law. The practice of exposure was common in republican Rome: the law is doubtful. The street called Velabrum (*Juvenal*, Sat. vi.), and the column called Lactaria (from this circumstance, according to some antiquaries) were places usually selected for the purpose. Abandoned children were declared by law to be the slaves or absolute property of those by whom they were brought up; and several were saved from death, not from humane motives, but that their foster-fathers might, by mutilating their persons and exhibiting them in the streets, derive an infamous livelihood from the alms given them by the passengers. At length the progress of Christianity put an end to these disgusting enormities. The exposure of children was made a punishable offence in A. D. 374; and their slavery was abolished by an edict of Justinian in 530.

Infanticide has most properly been prosecuted with the utmost rigour, and made a capital offence in almost all modern countries. But it was early supposed that were the exposure or abandonment of children wholly prohibited, there would, despite of all that could be done to prevent it, be a great deal of infanticide. In consequence of the prevalence of this feeling, it has been customary in the Christian world, from a very remote period, to connive at the abandonment of children, and to provide means for the support of those that might be abandoned; and hence the origin of Foundling Hospitals.

The first distinct trace of an express foundation for foundlings is at Milan in 787. In 1070 the order of Brothers of the Holy Ghost was established, with the express purpose of taking care of sick, orphans, and foundlings. After that time this species of foundations rapidly multiplied in every part of Europe. But while private beneficence was thus exerted in their behalf, the church, which in the earlier period had undertaken the general care of them, seems by degrees to have thrown on the commonalty, in most European countries, the charge of nourishing such as were not received into any of the foundations. Traces of legal contests between the religious and civil establishments on this subject are to be found in the history of France through the whole 16th century. The uncertain state of the law rendered their preservation in that country extremely precarious. St. Vincent de Paule, in the 17th century, undertook their cause; and the foundation of the great Foundling Hospital of Paris, in 1670, is due to his efforts. In the provinces, and in most Catholic countries, and in those under the Greek church, public charity took the same direction.

It has been customary in these establishments to receive all children brought to them, without inquiring whether they were the fruit of regular marriages or of illicit amours! It seems idle to deny that the multiplication of such establishments, by providing a ready method for disposing of children, must have hindered a few cases of infanticide; but the injury they have done to public morals, and the waste of human life that they have occasioned, are ten times greater evils than any they have obviated. It is long, indeed, since well informed persons in this and other countries were aware of the pernicious tendency of foundling hospitals; and it is probable that, at no very distant period, they will be every where suppressed. In France the multiplication of these hospitals, and of exposures, has called at last the attention of the public to the frightful immorality, mortality, and expense which attend it. In 1680, ten years after its foundation, the great hospital at Paris admitted 890; in 1750, 4000; in 1830, nearly 8000. In all France there were nourished at the public expense, in 1784, 40,000 children; in 1809, 69,000; 1826, 118,000. The number is now about 130,000. It varies greatly in the different departments; being greatest in the north, centre, and south; least in the eastern departments bordering on Germany, and in the western, or Britanny, La Vendée, &c. And the statistics of France plainly show, as Messrs. Terme and Montfalcon, the authors of the most comprehensive work on the subject, explicitly declare, that it is "not poverty, but luxury, which produces exposures." The two great measures for reducing the burden which have lately been partially put in execution, are the sup-

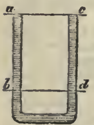
pression of the turning-boxes, or, in other words, rendering the abandonment *public;* and the removal of the new-born children into another department, which, it is said, always produces, when tried, a great reduction in the number of exposures. In Italy, Belgium, &c., similar institutions prevail, and a similar increase of burden has of late years been felt. It has, no doubt, been augmented by the improvement which has taken place in the management of these unfortunate creatures. Formerly death soon relieved the institutions of their maintenance. Towards the end of the last century, 80 per cent. of the children are said to have died at Paris in a single year; 90 at Marseilles; 91 at Dublin. The mortality is now much diminished; though it is thought that in France nearly 60 per cent. still die in their first year. The whole number of children annually exposed is said to be, at St. Petersburgh, about 45 per cent. of those born; Rome, 28; Lisbon, 26; Vienna, 23; Paris, 21. In England, Captain Thomas Coram is celebrated for his establishment of the Foundling Hospital in 1739. It was extremely popular at the time, and for many years was assisted by frequent votes of parliament. Similar institutions were projected in other parts of the country; but the enormous increase of abandonments, and the expense which they occasioned, produced such an alteration in public opinion, that the system of the Foundling Hospital was entirely altered; and, notwithstanding its name, it is now destined merely for the reception of orphans. Abandoned children in England become burdens to the parish in which they are found.

We may remark, by the way, that the statements now laid before the reader, as to the injurious influence of foundling hospitals, strikingly corroborate the principles laid down in the article FOUNDATIONS, as to the necessity of the legislature exercising a certain control over the property left to promote what is believed to be at the time a charitable or benevolent purpose. (See *Gouroff, Essai sur les Enfans Trouvés*, 1819; *Quart. Rev.* vol. xi.; *L'Abbé Gaillard, Recherches*, 1837; and the excellent work of Messrs. Terme and Montfalcon, already cited, *Histoire des Enf. Trouvés*, 1837.)

FOUNT. (Fr. fonds.) The quantity of types of any particular sort in a printing office, whether it be great or small. Thus a small fount may consist of fifty or one hundred pounds weight, comprising the usual proportion of the various letters of the alphabet; and a large fount of thirty thousand or forty thousand pounds weight, or more.

FOU'NTAIN. (Lat. fons.) By this term is designated any natural or artificial apparatus by means of which water springs up. In natural fountains the ascensional effort is produced by the hydrostatic pressure of the water itself; in artificial fountains it is produced either by the same pressure, or by that of compressed air, or sometimes by machinery.

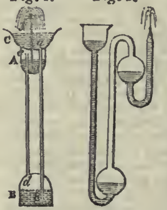
The theory of natural fountains is extremely simple, and depends on the well-known property of fluids — that, when enclosed in tubes or vessels communicating with one another, the fluid rises to the same level in all of them; and that its pressure on the sides of the tube at any point is proportional to the height of the vertical column above that point. Suppose *a b* and *c d* to be two pipes communicating with each other, and that water is poured into the first at *a;* it will ascend equally in both tubes, though they may be of very different sizes, and stand at the same level *a c*. Let us now suppose the tube *c d* to be cut away at *d*, and let the line *b d* be horizontal; then the pressure at *d* being the same as at *b*, the water will spring from *d* with a velocity $V = 2\sqrt{gh}$, where g is the accelerating force of gravity (equal to 32 feet in a second of time), and h is the altitude of the column *a b*. (*See* HYDRODYNAMICS.) The water, therefore, if it suffered no resistance from the air, or other impediment, would spring up from *d* to *c*.



Now it is precisely on this principle that all natural fountains are explained. The rain which falls from the atmosphere is absorbed in three different ways. One part of it collects in rills on the surface of the ground; these unite in streams or rivulets, which flowing into one another form rivers, and thus it is conveyed to the ocean. A second part is taken up in giving humidity to the soil, from which it is returned to the atmosphere by evaporation. A third portion descends into the earth, through soils of a spongy or porous nature, or through crevices and interstices in the strata, until it meets, frequently at a very considerable depth, with strata through which it cannot penetrate, and is then collected in subterraneous reservoirs. When confined in this manner it is subject to the pressure of the water which fills the channels through which it has descended; and when this pressure is sufficient to overcome the resistance of the superincumbent mass of earth, the water breaks through the superficial strata, and gushes forth in a spring. But if the strength of the superincumbent materials exceed the hydrostatic pressure, the water will remain stored up as it were in the subterraneous reservoir. Now if the ground above such a reservoir, or any channel communicating with it, be perforated, the water, having free access to the opening, will rise in it till it attains the level of the highest part of the channels from which it is supplied. If this level is above the surface of the ground, the water will have a tendency to rise; and when the ascensional force is considerable, it may by proper means be formed into a fountain. That subterraneous reservoirs formed in this manner exist in great abundance, and at great depths under the surface, we have sufficient evidence in the facility with which water may be obtained in almost all countries from *Artesian Wells*.

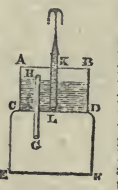
FOUNTAIN OF HERO. An ingenious hydraulic machine, of which the invention is ascribed to Hero of Alexandria, who lived about 150 years before our era. Its principle depends on the transmission of the pressure sustained by a body of water in one vessel to that in another by means of the elasticity of air. The essential parts of the apparatus consist of two close vessels, A and B, the first placed at some height above the other, and connected by a frame; and of three tubes or pipes, of which the first, *a b*, descends from a basin C to very near the bottom of the lower vessel B; the second, *c d*, rises from the summit of the vessel B to the top of A; the third, *e f*, rising from the lower part of A to some height above A, and forming the jet at *f*. Conceive the vessel A to be filled with water, and B with air. In this disposition of the apparatus, let water be poured into the basin C; this will descend through the pipe *a b*, and gradually fill the vessel B. But as it rises in B the air in that vessel escapes through the pipe *c d*, and is compressed at the top of A, and, by its spring or elasticity, forces the water through the tubes *e f*, and thus produces a jet at *f*, which will continue until the vessel A is nearly emptied, or B nearly filled. The force which produces the jet is equal to the pressure of a column of water, the height of which is equal to the difference of the levels of the water in C and B: according to theory, therefore, the water should spout to a height above its level in A equal to that distance.

Fig. 1. *Fig.* 2.



The second figure represents the fountain of Hero in another form. An apparatus constructed on this principle is employed for draining the water from the mines of Schemnitz in Hungary.

Artificial fountains are also produced by means of the elasticity of heated air, or of air condensed by any other means. Two different apparatus for this purpose are frequently met with in cabinets of natural philosophy. The first consists of two close vessels of tin, placed the one above the other, the lower one, C D E F, being of a considerable size; and the upper, A B C D, furnished with a tube or jet, K L, which reaches to near the bottom of the vessel. On applying the heat of a lamp to the lower vessel, the air within it expands, and making its way through the open tube G H is compressed at the top of the vessel A B C D, and thus by its pressure forces the water in that vessel through K L, forming a small jet at K. This apparatus being generally constructed in the form of a temple, produces a very pleasing effect.



The other apparatus to which we have alluded exhibits the appearance of a *fire-fountain*, and when neatly constructed forms an exceedingly elegant toy. On a pedestal of wood or metal, a glass globe with a pretty long neck, from the middle of which spring two branches, A and B, is placed in an inverted position, the globe being first filled with spirits of wine, and the neck well corked. The pressure of the atmosphere prevents the fluid from escaping at the orifices of the tubes A and B, while the temperature is undisturbed; but on applying the flame of a taper to the drops which form at these orifices, the globe is heated; steam is formed at the upper part, the elastic force of which causes the spirit to spring from the orifices, and this taking fire heats the globe to a still greater degree, and increases the action, so that two beautiful jets of burning spirit of wine are produced. As the pressure of steam is very apt to burst the globe, the exhibition of this experiment is attended with some danger.

FOURTH. In Music, one of the harmonical intervals; so called because it contains four sounds or terms between its extremes, and three intervals; or as being the fourth in order of the natural or diatonic scale from the fundamental.

FOVI'LLA. In Botany, the matter contained within the grains of pollen.

FOWLING. The art of catching birds with nets, birdlime, decoys, or other devices. It is also used for taking birds with hawks, falcons, and other birds of prey; more properly called falconry and hawking. In Latin this sport was called aucupium; from avis, *a bird*, and capio, *I take*.

FOX. *See* VULPES and CANIS.

Fox. A particular kind of strand made of rope-yarns.

FO'XGLOVE. The *Digitalis purpurea*; a common indigenous plant, the leaves of which, when carefully dried and powdered, or made into a tincture or infusion, are used in medicine. In small and repeated doses it lowers the pulse in an extraordinary manner, and produces debility and fainting: combined with other remedies, it forms an ingredient in some powerful *diuretics*.

FRA'CTION, in Arithmetic, is an aliquot part of unity. In order to form a precise idea of a fraction of any unit, we must consider the unit to be divided into a certain whole number of equal parts, of which parts we take one, two, three, &c.: the number of parts so taken is what constitutes the fraction. The expression of a fraction therefore necessarily involves two whole numbers; namely, one to denote the number of parts into which the unit is divided, and the other to express how many of these parts are to be taken to form the fraction. The first of these numbers is called the *denominator*, and the second the *numerator*. Thus, *seven eighths* of a foot, *five twelfths* of a pound, are fractions. In the first we suppose the foot or unit to be divided into eight equal parts, of which seven are taken; so that eight is the denominator and seven the numerator. In the second the unit or pound is supposed to be divided into twelve equal parts, of which five are taken; here twelve is the denominator and five the numerator. From these considerations it results that a fraction is a magnitude referred to a certain part of the principal unit, which part may itself be considered as a particular kind of unit. Thus the fraction *seven eighths* of a foot being the same as seven times the eighth part of a foot, this eighth part is a particular unit which the proposed fraction contains eight times. Hence two fractions are said to be of the same kind when their denominators are the same. For example, *five twelfths*, *six twelfths*, *eleven twelfths*, are fractions of the same kind; but *two thirds* and *three fourths* are fractions of different kinds, because their denominators are different.

In order to express fractions by the numerical digits, the numerator is placed over the denominator, with a line or bar between them. Thus the fraction three fourths is written $\frac{3}{4}$, five twelfths $\frac{5}{12}$, &c. Reciprocally, $\frac{13}{15}$, $\frac{17}{20}$, &c. designate the fractions thirteen fifteenths, seventeen twentieths, &c.

A fraction may also be regarded as the quotient that arises from the division of its numerator by its denominator. For example, the expression *seven eighths*, or seven times the eighth part of unity, is identical with the expression *the eighth part of seven*, or *seven divided by eight*.

From the definition which we have given of the numerator and denominator of a fraction, the following consequences result: — 1. If, without altering the denominator of a fraction, we multiply or divide its numerator by any number, the new fraction will be so many times greater or less than the original fraction. 2. If, without altering the numerator, we multiply or divide the denominator of a fraction by any number, the new fraction will be so many times smaller in the former case, and so many times greater in the latter, than the original fraction. 3. The value of a fraction is not altered by multiplying or dividing both numerator and denominator by the same number. It is on these three principles that the practical rules for the addition, subtraction, multiplication, and division of fractions are grounded.

Addition and Subtraction of Fractions. — In order that two fractions may be added together, or the one subtracted from the other, it is necessary that they be both of the same kind, or denomination; for it is only homogeneous things that admit of amalgamation. The fractions $\frac{2}{3}$ and $\frac{3}{4}$ cannot be added together in their present form, because they are of different denominations. But fractions can always be reduced to the same denomination, or to a common denominator, by means of the third principle above laid down; for numbers can always be chosen such that if we multiply the terms of each fraction by them severally, the resulting equivalent fractions will have the same denominator. Thus, multiplying the terms of the fraction $\frac{2}{3}$ by 4, we get the equivalent fraction $\frac{8}{12}$; and multiplying the terms of $\frac{3}{4}$ by 3, we get the equivalent $\frac{9}{12}$. The two proposed fractions are therefore reduced to the two others, $\frac{8}{12}$ and $\frac{9}{12}$, the sum of which is $\frac{17}{12}$, and the difference $\frac{1}{12}$. When any number of fractions are to be added together they are most conveniently reduced to a common denominator by this rule: — Find the least common multiple of all the denominators; divide this multiple by each of the denominators one after the other; and multiply the terms of the proposed fractions respectively by the corresponding quotients thus found; the results will be a series of equal fractions, all having the same denominator, and this expressed by the lowest possible number. When this operation has been performed, the sum or difference of the fractions is obtained by placing the sum or difference of their numerators over the common denominator.

Multiplication of Fractions. — Let it be proposed to multiply $\frac{3}{5}$ by $\frac{6}{7}$. As the multiplier $\frac{6}{7}$ is equal to six times the seventh part of unity, it is obvious that the product must be equal to six times the seventh part of three-fifths. Now by the second principle above laid down, the seventh part of $\frac{3}{5}$ is found by multiplying the denominator by 7; this gives $\frac{3}{35}$. And in order to obtain a fraction six times greater than $\frac{3}{35}$, we must multiply the numerator by 6, which gives $\frac{18}{35}$ for the product required. Hence for the multiplication of fractions we have this rule: — Multiply all the numerators together for the numerator of the product, and all the denominators for its denominator.

As a whole number can always be expressed in the form of a fraction by placing 1 under it for a denominator, this rule includes all the different cases.

Division of Fractions. — Let it be proposed to divide $\frac{3}{5}$ by $\frac{8}{11}$. Here the divisor $\frac{8}{11}$ being equal to 8 times the 11th part of unity, the dividend $\frac{3}{5}$ must (from the nature of division) be equal to 8 times the 11th part of the quotient. But, by the second principle, the 8th part of $\frac{3}{5}$ is $\frac{3}{40}$, therefore $\frac{3}{40}$ is the 11th part of the quotient required; consequently 11 times $\frac{3}{40}$, or $\frac{33}{40}$, is the quotient itself. Hence we deduce the general rule for the division of one fraction by another: — Multiply the numerator of the dividend by the denominator of the divisor, the product will be the numerator of the quotient; and multiply the denominator of the dividend by the numerator of the divisor, the product will give the denominator of the quotient required. It is obvious that this amounts to the same thing as to invert the terms of the divisor, and then proceed as in multiplication.

Fractional expressions are divided into several kinds: — proper and improper, simple and compound. A *proper fraction* is one whose numerator is less than its denominator, and its value consequently less than unity. An *improper fraction* is one whose numerator is equal to or greater than its denominator, and its value consequently equal to or greater than unity. A *simple fraction* is an expression consisting of one fraction only. A *compound fraction* is a fraction of a fraction, or a fractional part of some whole or mixt number. And a *mixt number* is an expression consisting of a whole number and a fraction.

The fractions of which we have now spoken are common or *vulgar* fractions; when the denominators are 10, 100, or in general any power of 10, they become *decimal* fractions, and are expressed by a different notation. *See* DECIMAL.

FRA'CTURE. (Lat. frango, *I break*.) In Mineralogy. When minerals are broken, they either exhibit a smooth regular surface, to which the term *cleavage* is generally applied; or they give an irregular or uneven surface, termed a *fracture*. Werner, who first employed this character in his description of minerals, divides their various fractures into compact, fibrous, radiated, and foliated. The terms *earthy*, *granular*, *uneven*, *hackly*, and *splintery*, the meanings of which will be sufficiently obvious, are employed by other mineralogists.

FRACTURE. In Surgery, this term is limited to broken bones. Such accidents are generally the result of external force; but it occasionally happens that the powerful action of certain muscles may cause a fracture, as is frequently the case in regard to the *patella* or knee-pan. Fractures are distinguished by surgeons into *transverse*, *oblique*, and *longitudinal*, depending upon the direction in which the bone is broken; and into *simple* and *compound*, dependent upon the circumstances with which the injury is accompanied. "By *simple fracture* surgeons mean a suddenly formed breach in the continuity of one or more bones, without any external wound communicating internally with the fracture; by a *compound fracture* they signify the same sort of injury of a bone or bones, attended with a laceration of the integuments, which laceration may be produced by the protrusion of one or both ends of the fracture through the skin, or by a ball or other body which enters or otherwise wounds

the soft parts at the same moment that it breaks the bone."

The history and treatment of fractures is an extensive and important department of surgery, upon which several treatises have been written by very eminent practitioners. An excellent article upon the subject will be found in *Cooper's Surgical Dictionary*, from which work we have borrowed the above definition.

FRAISE. In Fortification, a kind of defence which is formed by driving pointed stakes at a small angle with the horizon into the retrenchment of a camp, &c.

FRAMBŒ'SIA. (Framboise, *a raspberry*.) The yaws; a disease endemic in the Antilles and some parts of Africa, which is attended by cuticular excrescences something like mulberries, which discharge a watery fluid. It is contagious, but not dangerous.

FRAMING. (Sax. ꝼpamman, *to form*.) In Architecture, the rough timber-work of a house, including floors, roof, partitions, ceilings, and beams. Generally, any pieces of wood fitted together with mortices and tenons are said to be framed; as doors, sash frames, sashes, &c.

FRA'NCHISE. In Law, a species of incorporeal hereditament, synonymous with liberty, which is defined "A royal privilege, or branch of the king's prerogative, subsisting in the hands of a subject." For an account of the nature of the *elective franchise*, see PARLIAMENT.

FRANCI'SCANS. One of the four Mendicant Orders, founded by St. Francis of Assisi, in Umbria, in the year 1209. *See* art. ORDERS, MENDICANT.

FRANK. A coin in use in France, equivalent to 9·69*d*. *See* MONEY.

FRANK. A privilege enjoyed by the members of both houses of Parliament, some government offices, and certain public functionaries, of sending and receiving a certain number of letters *post free*; abolished Jan. 10. 1840. *See* POSTAGE.

FRANK ALEU. In Law, an absolute right to real estate in Lower Canada, and also in Guernsey and Jersey, acknowledging no feudal superior, and consequently not a *tenure*. *See* ALLODIUM.

FRANKALMOI'GN. (From two Norman-French words, signifying free alms.) In Law, a tenure by spiritual service, where an ecclesiastical corporation, sole or aggregate, hold land to them and their successors of some lord and his heirs in free and perpetual alms. Donations in Frankalmoign are now out of use, as none but the king can make them; but they were expressly excepted from the operation of stat. 12 C. 2. c. 24., which abolished military tenures.

FRANKINCENSE (said to be so called from its liberal distribution of odour). The gum-resin *olibanum*, which is the produce of the *Boswellia serrata*, and imported from the Levant, bears the commercial name of *frankincense*. When it is burned, or sprinkled upon hot coals, it exhales a very fragrant and diffusible odour.

FRA'NKPLEDGE, or FREEBORG. (German bürge, *pledge*.) A celebrated Anglo-Saxon usage, which appears to have been of two kinds. 1. That which may be termed *seignorial frankpledge*, by which every lord (hlaford) was rendered responsible for the appearance of his own *men* or dependants, when accused before justice, in the hundred court; when, if the party absconded, the lord became liable to the king in the amount of the "were" or amercement for the offence. 2. Collective or public frankpledge, which is the sense in which the word is most commonly used by modern writers, is of very obscure origin, but appears to have existed after the Conquest in the southern and eastern parts of England. The burghers and ceorls, or inferior class of freemen, were enrolled in small collective bodies termed tythings or decennaries (in many instances equivalent to the townships), under the superintendence of a chief pledge or tything-man. The tything thus organized was bound for the appearance of any one of its members under accusation. The "view of frankpledge" originated in the usage of calling together the individuals who were enrolled in each of these bodies at certain stated times; which were usually held at the court leet, but were not (as Blackstone states it) the main object of that institution, since courts leet were held from an early period in the northern parts of England, in which frankpledge never existed, as well as in the southern. On the view of frankpledge, the members of each tything also took the oath of allegiance under the Norman kings. (See *Turner's Anglo-Saxons; Sir F. Palgrave's Commonwealth of England*; and art. COURT LEET.)

FRANKS. A general appellation conferred by the Turks and other Asiatic nations on all the inhabitants of Europe.

FRATE'RCULA. The generic name for the puffins. *See* MORMON.

FRATERNITIES, were associations of laymen in the middle ages, formed for the purposes of general benevolence, and for the discharge of other Christian duties.

FRAUD, in Law, is the general name for any species of deceit in contracts, either by suppression of truth or assertion of falsehood. The most complete definition of it is that given by Forbes: — "Dolum malum esse omnem calliditatem, fallaciam, machinationem, ad circumveniendum, fallendum, decipiendum alterum adhibitum." (*Story's Commentaries on Equity Jurisprudence*.) With a view to the provisions of the English law, frauds may be divided into such as are cognizable by courts of common law, such as are cognizable in equity only, and such as are expressly provided against by statutes. It has been laid down as a general principle, that courts of common law can relieve against the consequences of fraud (by making contracts void, &c.) as well as courts of equity, wherever the fraud is clearly established; and that their inadequacy to provide a proper remedy arises only from their inability to attain the necessary evidence. But however this may be, it has long been a general principle, that courts of equity, in the language of Lord Coke, have jurisdiction over frauds, covin, and deceits, for which there is no remedy by the ordinary course of law. Hence arises one of the three great branches of equity jurisdiction — trust, fraud, account. (*See* CHANCELLOR.) The general principles of that jurisdiction appears to be, that the courts will relieve, by considering acts as performed of which the performance has been fraudulently prevented; by setting aside bargains made in ignorance of rights, or where there is material concealment of title, value, &c.; or, finally, misrepresentation in material particulars. Various acts have been made fraudulent, so as to produce the consequence of annulling contracts and avoiding conveyances by statutes: *e.g.* conveyances with intent to defraud creditors, by 13 Eliz. c. 5.; voluntary conveyances, 27 Eliz. c. 4.; various contracts, conveyances, &c. not executed with the formalities required by the Statute of Frauds, 29 C. 2. c. 3. Some frauds are of a criminal nature, and punishable by indictment; but they are chiefly such as affect the public, or such as are effected by means of false tokens.

FRE'CKLES. Small yellow specks and spots which appear upon the face, especially of fair persons much exposed to the weather. The best application is a dilute spirituous lotion (one part of brandy to eight of water), with a few drops of muriatic acid, so as to render it just perceptibly sour.

FREE'BOOTERS. (Germ. freibeuters, Fr. flibustiers.) A name given to some adventurers of all nations, but especially of France and England, who have obtained a place in history by the courage and intrepidity which they displayed in executing the most difficult enterprises. The origin of their history is merged in obscurity, and it is impossible to ascertain precisely whence their name is derived; but the *flibustiers* of the French naval historians are identical with the *buccaneers* of our own language. (*See* BUCCANEERS.) The South American islands formed the chief theatre of their depredations; and such was the relentless hostility with which they visited the Spaniards, that during the latter half of the 17th century, which embraced the most formidable period of the freebooters' career, their commercial operations in the Indian seas were nearly destroyed. At the commencement of the 18th century, the freebooters sustained in their expeditions a series of disasters, which sensibly diminished their numbers; and since that period the designation has been applied indiscriminately to any individual who regards "the universe as his property," and appropriates to himself either furtively or forcibly the possessions of another.

FREE'HOLD, in Law, is a term which is used in two different senses: 1. To express the quantity of estate which a man may have in lands or tenements; and, 2. To express a tenure by which lands and tenements are held. Thus, an estate of freehold, to satisfy the full acceptation of the term, must be both sufficient in quantity of interest and sufficient in tenure.

1. As to quantity of interest, all estates for a term uncertain in duration are estates of freehold; and they are divided into estates of inheritance, and not of inheritance. The first of these are either absolute (fee-simple) or limited (fee-tail, or fee-simple conditional). The second are estates for life, or for an uncertain period limited within the term of a life; as, an estate granted to a widow durante viduitate. Such estates as this are by the law regarded as estates for life, determinable on a given event. 2. With respect to tenure, freehold tenure is derived from the ancient free socage; and lands held by copy of court roll according to the custom of a manor, viz. copyholds, are not within this denomination. But lands held by custom of the manor, *not* by copy of court roll, are not copyholds, but customary freeholds.

In order, therefore, to give the privileges or impose the duties attached by the law to freeholders (such as serving on juries, voting at county elections, &c.), the estate in respect of which such right or duty attaches must be either for life or a greater interest, and must be held in freehold tenure.

FREEMA'SONRY. A well-known institution, the origin of which has given rise to much fabulous narrative and idle speculation. Some derive the mysteries of Freemasonry from those of the priests of Eleusis, and these

again from Egypt; others from the secret associations of the Templars. (*See* TEMPLARS, BAPHOMET.) The last opinion was illustrated at great length by M. Barruel (*Memoires du Jacobinisme*), who conceived both Freemasons and Jacobins to be the relics of a long-established conspiracy for the subversion of religions and empires. But our distinct historical information merely amounts to this, that the fraternity of architects or builders in the middle ages extended over all Catholic countries, and was especially patronized by the see of Rome. It is to this craft that we owe the magnificent Gothic edifices dedicated to religion, which contrast so strongly with the barbarous efforts of those ages in most other departments of art. It is said that this association was introduced into Scotland in the 13th century, and about the same time into England, it being ascertained that the Abbey of Kilwinning in the former country was raised by this fraternity; and it is believed to have continued to exist, although small in number, in these two countries after it had disappeared from the Continent. The Kilwinning and York lodges are respectively the most ancient in either country. But the mode and period in which the association became changed from a mere professional fraternity to a society of persons of all descriptions connected by secret symbols, is unknown. It certainly excited great attention, and numbered individuals of high rank as honorary members, as early as the 15th century. The Scottish masons appointed St. Clair of Roslin their hereditary grand-master in 1630; and the office was resigned by his descendant in 1736, when the grand lodge of Scotland was instituted. In 1725, the first French lodge was established; in 1730, the first American; in 1735, the first German. From that period until the present, while the society has existed among ourselves as a mere convivial and benevolent association, and has been patronized even by royalty and the nobility, it has been subjected on the Continent to a variety of suspicions; and it is most probable that political intriguers have availed themselves of the secrecy afforded by it to further their schemes. Indeed, in this country, the "Royal Arch" degree is said to have been devised by the Scottish Jacobites. Pope Clement XII. excommunicated the Freemasons in Spain and Portugal: until recent events, their name was synonymous with that of deists and revolutionists. But the most singular chapter in the history of the society relates to its fortunes in America; where it has given origin to two violent political parties. The story of the abduction and murder of a certain William Morgan, suspected of having revealed the secrets of the fraternity, made a great sensation in the Union, and is not cleared up at this day. The reader will find it detailed and commented on in Miss Martineau's recent work. (See *Lawrie's History of Freemasonry*, Edin. 1804; *Anderson's* ditto; *Preston's Illustrations of Masonry*; the *Freemason's Quarterly Magazine*; the German *Freimaurer Encyclopædie*, &c.)

FREE'THINKER. A term, usually of reproach, applied to those who reject the ordinary modes of thinking in matters of religion. It is almost synonymous with *Deist*, which see.

FREEZING. *See* FROST.

FREEZING MIXTURES. When five parts of powdered nitre and five of powdered sal ammoniac are mixed with sixteen parts of water, the thermometer falls in the mixture from 50° to about 10°; so that in this way a degree of cold much below the freezing point of water may be artificially and cheaply obtained, for the salts may be again procured by evaporation and used repeatedly. When ice or snow can be obtained, the most effective freezing mixture is produced by mixing it with about half its weight of salt; it carries the thermometer nearly to 0°. The utmost degree of cold produced by the skilful combination of the best freezing mixtures has not exceeded 140° below 0°.

FREIGHT. In Mercantile Law, the sum paid by the merchant or other person hiring a ship, or part of a ship, for the use of such ship or part for a specified voyage, or for a specified time. Freight must be mentioned, eo nomine, in a policy of insurance, and is not covered by a policy on goods.

FRE'SCO PAINTING. (It. fresco, *fresh*.) In Painting, a method of painting by incorporating the colours with plaister before it is dry, by which it becomes as permanent as the wall itself. This method of painting is extremely ancient. It was used by the Greeks, and can be traced even to Egypt. From difficulty of alteration when the colour is once absorbed, the greatest precision of design is necessary before commencing the work.

FRET, or FRETTE. (Etymology doubtful.) In Architecture, a species of ornament consisting of one or more small fillets meeting in vertical and horizontal directions. The section of the channels between the fillets is rectangular. The subjoined diagram shows two sorts of simple frets; but they are often much more complicated.

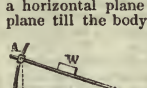
FRETS. The cross bars on the finger boards of stringed instruments of ivory or brass, by pressure whereon with the finger the string is stopped to produce a certain note in the scale. The use of frets is still continued on the Spanish guitar, and was formerly in constant use upon what was called the bass-viol for learners, and taken off when they had learnt by practice to measure the accurate distance of the stops. On lutes and viols they were always permitted to remain.

FRIAR. (Lat. frater, *brother*.) A brother or member of any religious order; but more exclusively applied to those of the Mendicant Orders, of which the four chief were the Dominicans, Franciscans, Carmelites, and Augustines. *See* ORDERS, MENDICANT.

FRI'CTION. (Lat. frico, *I rub*.) In Mechanics, the resistance produced by the rubbing of the surfaces of two solid bodies against each other. If the surfaces of bodies were perfectly smooth and polished, they would slide along one another without suffering any resistance from their contact, and all the simple relations between power and resistance determined by theory in respect of the different machines would hold good without any modification whatever. But this state of perfect polish never exists. The surfaces of all bodies with which we are acquainted, even when most carefully polished, retain a greater or less degree of asperity, which prevents them from sliding over one another without impediment; and in many cases the resistance thus created amounts to a large proportion of the whole resistance to be overcome. In order, therefore, to ascertain the real value of the effect of powers applied to machinery, it is necessary to determine the amount of the friction, and to add this new resistance to that which is given by the theory of mechanics.

The determination of the laws of friction, and its amount with respect to particular substances, have occupied the attention of many experimental philosophers and mathematicians, as Amontons, Euler, Desaguliers, Vince, &c.; but the first complete set of experiments on the subject was made by Coulomb about the year 1780. His results, though they have been partly modified by subsequent experiments, throw much light upon the subject, and are of great value to the practical engineer.

There are two modes by which the nature and operation of friction may be ascertained. The first is very simple, and consists in merely placing a heavy body W on a horizontal plane A B, and elevating the end of the plane till the body begins to slide. When this motion commences, it is evident that the force of gravity just begins to exceed the resistance occasioned by the friction, and as the gravity is known from the weight of the body and the inclination of the plane, we have thus the means of comparing the friction with a given force.



For let A E be drawn perpendicular to the horizontal line C B; then, since the weight, the friction, and the pressure make equilibrium, if we take A B to represent the weight W, the force down the plane (which is equal to the friction) will be represented by A E, and the pressure perpendicular to the plane by B E. Hence, putting $P =$ the pressure, $F =$ the friction, and $i =$ A B C, the inclination of the plane, we have $P = W \cos. i$, $F = W \sin. i$, and consequently $F = P \tan. i$. The angle i is called the *limiting angle of resistance*; and $\tan. i$, or the ratio of friction to pressure, is called the *co-efficient of friction*.

But this method is liable to some uncertainty. Most bodies, after having been in contact for some time, require a greater force to originate than to keep up progressive motion; but it is obvious that the inclination of the plane of descent marks only the initial obstruction. Coulomb accordingly adopted a different mode of proceeding. His general method was to draw a sort of loaded sledge along a horizontal bench, by means of weights placed in a dish attached to the sledge by a cord passing over a pulley. The sledge was mounted on sliders of the substance on which the experiments were to be made; and corresponding slips of the same or a different substance placed under the sliders on the bench. This apparatus has been called a *tribometer*. The following are some of the results which were obtained:—

Assuming the pressure as equal to 100 parts, the friction of oak against fir was 66 in the direction of the fibres, but amounted only to 16 when moved with the velocity of a foot each second; the friction of oak against oak in the direction of the fibres was 43, and across them only 27, the effect being still reduced by motion to 10; the friction of fir against fir in the direction of the fibres was 56, which sunk to 17 during motion; the friction of elm against elm in the direction of the fibres was 46, and reduced by motion to 10. On the other hand, the friction of copper upon oak, lengthwise, was 8 at the commencement of the motion, but increased to 18 when the velocity was a foot in a second; the friction of iron upon oak with the initial velocity was 11, and was increased by the motion to 18. But the mutual friction of metals appeared in general to be scarcely, if at all, affected by motion. In these experiments no unguents were used.

Where metals rub against wood, it is necessary that the two bodies continue longer in contact, in order that the friction may acquire its maximum. In the case of iron against wood at least 4 or 5 hours must elapse before the momentary increase of friction disappears; whereas in the case of wood against wood a single minute was sufficient. But the resistance appears to increase by contact, though less sensibly, even for several days. The application of grease to the surfaces of wood produces a similar effect, and the resistance does not attain its maximum till after a very considerable time. At the end of 5 or 6 days the resistance is perhaps 14 times greater than it was at the first instant, if the surface of contact is considerable in respect of the pressure; but when the surface is small, the friction reaches its maximum much more quickly.

An important part of the investigation was to ascertain whether the friction is increased by the velocity of the rubbing bodies. With respect to bodies of the same kind descending on inclined planes, Coulomb found that the time required for passing over the first half was a little more than double that required for passing over the second. But a body put in motion by a constant accelerating force employs for passing over one space, and over two equal consecutive spaces, times that are to each other in the ratio of $\sqrt{1} : \sqrt{2} = 100 : 142$; that is to say, if 100 units of time are consumed in passing over the first space, 142 will be consumed in passing over the first and second together, and consequently 42 in passing over the second. Now this agrees as nearly as possible with the result of the experiments; consequently we infer that a load drawn along a smooth plane by a constant accelerating force (that of a descending weight for example) is uniformly accelerated. But this requires that the friction, at every instant, destroys only a proportional quantity of the force added by the constant action of gravity. The conclusion, therefore, is, that, for moderate velocities at least, *the resistance due to friction is a constant quantity*, and very nearly the same for every degree of velocity.

Another point of great importance was to ascertain the relation the friction bears to the pressure; for example, in what ratio the friction is increased by doubling or trebling the load. Coulomb found that when wood has been allowed to rest on wood for some time, without the intervention of any unguent, the resistance occasioned by the friction is proportional to the pressure. This resistance for a short time increases rapidly by the contact, but attains its maximum in a few minutes. The friction of wood sliding on wood with any velocity is still proportional to the pressure; but the resistance is much less in amount than that which is required to detach the surfaces after some minutes of contact. In the case of oak, for instance, the force required to detach the surfaces after being some minutes in repose is to that which is necessary to overcome friction alone after motion has commenced in the ratio of 100 to 23. The friction of metals on metals is also proportional to the pressure; but the intensity is the same, whether the surfaces have been any length of time in contact, at rest, or are gliding along with an uniform velocity.

The friction of heterogeneous substances, as wood and the metals, is entirely different from the above. In the case of wood against wood dry, or of metal against metal, the friction of the rubbing bodies is very little influenced by the velocity; but in the present case the friction increases very sensibly with an augmented velocity. Coulomb inferred that the friction increased as the natural numbers, when the velocities are increased as the squares of those numbers. In all cases of a hard body rubbing against a very soft substance, the friction increases remarkably with the velocity.

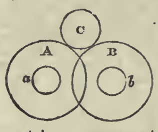
Since the friction is in general proportional to the pressure, it follows that it will not be altered by increasing or diminishing the extent of the rubbing surfaces. Nevertheless this consequence fails in the extreme cases. The friction is sensibly diminished when the surfaces in action are reduced to the smallest dimensions. Thus, while the friction of a ruler of brass against a similar one of iron is expressed by 26, it was found to be only 17 after the sledge had been mounted on 4 round-headed brass nails.

On the whole, the following conclusions may be stated as the general results of Coulomb's experiments respecting the friction of bodies *sliding* on each other.

1. Between similar substances, under similar circumstances, friction is a constant retarding force. 2. Friction is greatest between bodies whose surfaces are rough, and is lessened by polishing them. 3. It is greater between surfaces composed of the same material, than between the surfaces of heterogeneous bodies. 4. If the rubbing surfaces remain the same, the friction increases directly as the pressure. 5. If the pressure continue the same, the friction has no relation to the magnitude of the surface. 6. The application of grease in general diminishes the friction, though in very different degrees.

The obstruction which a cylinder meets with in rolling along a smooth plane is quite distinct in its character, and far inferior in its amount, to that which is produced by the friction of the same cylinder drawn lengthwise along a plane. For example, in the case of wood *rolling* on wood, the resistance is to the pressure, if the cylinder be small, as 16 or 18 to 1000; and if the cylinder be large, this may be reduced to 6 to 1000. The friction from sliding, in the same cases, would be to the pressure as 2 to 10, or 3 to 10, according to the nature of the wood. Hence, by causing one body to roll on another, the resistance is diminished from 12 to 20 times. It is therefore a principle in the composition of machines that attrition should be avoided as much as possible, and rolling motions substituted whenever circumstances admit.

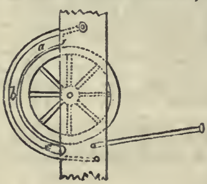
On this principle depends the advantage resulting from the application of *friction wheels* and *friction rollers*. The extremity of an axle C, instead of resting in a cylindrical socket, is made to rest on the circumferences of two wheels, A and B, to the axles of which, *a* and *b*, the friction is transferred, and consequently diminished in the ratio of the radius of the wheel A to the radius of the axle *a*. This ingenious contrivance appears to have first been applied by Henry Sully, in the year 1716. (*Descr. Abregée d'une Horloge, &c.*, Bordeaux, 1716.)



The following are deductions from Coulomb's experiments relative to the friction of rolling bodies: — 1. Like the friction of sliding bodies, it is a constant force. 2. It is affected by the nature of the surface so far as polish is concerned; but is not lessened by the interposition of unctuous substances. 3. It is less between heterogeneous than between homogeneous substances. 4. It is directly proportional to the pressure. 5. It has no relation to the magnitude of the surface. 6. It is much less than in the case of sliding surfaces, and varies in the inverse ratio of the diameter of the rolling body.

The friction of the axle of a wheel or pulley (whether the axle itself turns, or the wheel turns on the axle) is of a different kind from that of a cylinder rolling on a plane. It is less than that of sliding but greater than that of rolling bodies, and follows in all respects the laws of the friction of sliding bodies. A great advantage is here obtained by greasing the surfaces. By the application of fresh tallow the friction is reduced to one half.

Friction is one of the most effectual means of arresting motion. In some machines, especially wind-mills, cranes, &c., it is very important to have the power of suddenly stopping the machine, or at least of controlling its motion. This is effected by means of a strong bridle of wood or iron, *a*, *b*, *c*, fixed at one end, and at the other furnished with a lever, by pressing on which the bridle is brought into close contact with the broad rim of a wheel which participates in the general motion of the machine. The bridle may be made to bear on the whole circumference of the wheel; and a moderate pressure on the lever will produce a resistance sufficient to destroy the motion almost instantaneously.



Coulomb's experiments were also directed to ascertain the resistance arising from the rigidity of ropes when bent round rollers or cylinders. The results are as follow: — 1. The resistances of ropes are directly proportional to the tensions to which they are subjected. 2. The resistance increases with some determinate power of the diameter, and is greatest in ropes that have been strongly twisted, or are coated with tar. 3. The resistances are inversely as the diameters of the cylinders about which the ropes are bent.

When a rope is wound more than once round a cylinder, the resistance increases in a geometrical progression. This principle is frequently applied in practice: thus, in arresting the progress of a vessel, a rope is wound round a post, and a very few turns is sufficient to overcome any force which the rope is capable of withstanding.

A valuable series of experiments on friction was made some years ago by Mr. George Rennie, the details of which are given in the *Phil. Trans.* for 1829. The following are a few of the results: — Assuming as before the pressure equal to 100 parts, the friction of steel upon ice is 1·4; ice upon ice 2·8; hard wood upon hard wood 13; brass upon wrought iron 13·5; soft steel upon soft steel 14·6; leather upon iron 25; granite upon granite 30; yellow deal upon yellow deal 35; sandstone upon sandstone 36; woollen cloth upon woollen cloth 43. Some of the conclusions deduced by Mr. Rennie are as follow: — 1. In fibrous substances, such as cloth, friction is increased by surface and time, and diminished by pressure and velocity. 2. In harder substances, such as woods, metals, and stones, the friction is directly as the pressure,

without regard to surface, time, or velocity. 3. Friction is greatest with soft, and least with hard substances. 4. The effect of unguents is as the nature of the unguents, with reference to the substances to which they are applied.

In the *Memoires de l'Institut* for 1833, two very extensive sets of experiments are described, which were made by M. Morin, at Metz, under the auspices of the French government, for the purpose of verifying or correcting the results of Coulomb. In general, M. Morin's results differ widely in absolute amount from those of Coulomb, giving in some instances ratios three times as great; but they point to, and indeed fully establish, the same general conclusions. See Coulomb, *Théorie des Machines Simples* (Paris, 1821), and *Mem. des Savans Etrangers*, tom. ix. and x.; Ximenes, *Teoria e Pratica delle Resist. de Solidi ne' loro Attriti* (Pisa, 1782); Vince, *Phil. Trans.*, 1785; Rennie, *Phil. Trans.*, 1829; Morin, *Mem. de l'Institut*, 1833; *Ency. Brit.*, art. "Mechanics," &c.

FRICTION-WHEELS. See the preceding article.

FRI'DAY. (Germ. Freitag.) The sixth day of the week. The name is derived from *Freya* or *Friga*, a Saxon goddess. It is a fast day in the Romish church.

FRIE'NDLY SOCIETIES, or BENEFIT SOCIETIES. Voluntary associations of subscribers, for the purpose of forming a fund for the assistance of members in sickness, or other occasions of distress. It is supposed by Mr. Turner (in his *History of the Anglo-Saxons*), that the ancient guilds originated in associations of this description. "Of the various means that have been suggested in this view, and for enabling the poor to provide a resource against sickness and old age, none seem so likely to accomplish their object as the institution of friendly societies and savings' banks. The former are founded on a principle of mutual insurance. Each member contributes a certain sum, by weekly, monthly, or annual subscriptions, while he is in health; and receives from the society a certain pension or allowance when he is incapacitated for work by accident, sickness, or old age. Nothing, it is obvious, can be more unexceptionable than the principle of these associations. Owing to the general exemption from sickness until a comparatively late period of life, if a number of individuals under 30 or 35 years of age form themselves into a society, and subscribe each a small sum from their surplus earnings, they are able to secure a comfortable provision for themselves in the event of their becoming unfit for labour. Any single individual who should trust to his own isolated efforts would plainly be placed in an infinitely more hazardous position. Whenever an unfavourable contingency exists, the best and cheapest way of obviating its effects is by uniting with others, each subjecting himself to a small privation, so that none may be overwhelmed by any great calamity. However industrious and frugal, an individual, not a member of a friendly society, might not be able to insure his independence; inasmuch as the occurrence of any accident, or an obstinate fit of sickness, might, by throwing him out of employment, and forcing him to consume the savings he had accumulated against old age, reduce him to a state of indigence, and oblige him to become dependent on the bounty of others. Hence the paramount utility of the societies in question.

"For these and other reasons," says Mr. M'Culloch, "we are glad to find that friendly societies have been very widely introduced. There were enrolled from the 1st of January, 1793, to the commencement of 1832, no fewer than 19,783 such societies; of which 16,596 were in England, 769 in Wales, 2144 in Scotland, and 274 in Ireland. The societies existing in 1815 are said to have comprised 925,429 individuals. We have, however, some doubts as to the authenticity of this statement; but, if it may be depended on, the societies now in existence must comprise above 1,200,000 members! It should also be recollected that the progress of these societies, though great, and most honourable to the labouring population of Great Britain, has been not a little counteracted by the ignorance and mismanagement of their officers, and by the real difficulty of establishing them on a secure foundation. The great error has consisted in their fixing too high a scale of allowances. At their first institution they are necessarily composed of members in the prime of life; there is, therefore, comparatively little sickness and mortality amongst them. In consequence their funds rapidly accumulate; and they are naturally tempted to give too large an allowance to those members who are occasionally incapacitated. But the circumstances under which the society is placed at an advanced period are materially different. Sickness and mortality are then comparatively prevalent. The contributions to the fund decline at the time that the outgoings increase; and it has not unfrequently happened that the society has become altogether bankrupt; and that the oldest members have been left, at the close of a long life, destitute of all support from a fund on which they had relied, and to which they had largely contributed.

"But the errors in the constitution of friendly societies have been, in a great degree, amended. Various efforts, several of which have been productive of beneficial effects, have been made by private individuals and associations, and by the legislature, to obviate the chances of their failure, and to encourage their formation on sound principles. Two reports, by committees of the House of Commons, on the laws respecting friendly societies, printed in 1825 and 1827, supply a great deal of important and useful information; and the reports and tables published by the Highland Society are also valuable. There are, doubtless, several important points that still remain to be satisfactorily cleared up; but, in the mean time, enough has been done to enable government to interfere with effect in assisting the formation of friendly societies on a solid foundation. In this view several statutes have, at different times, been passed; but the act 10 Geo. 4. c. 56. repealed all previous statutes, and, with the act 4 & 5 Will. 4. c. 40., embodies the existing law upon the subject. All friendly societies, claiming the benefit of these acts, are obliged to submit a statement of their rules and regulations for the approval of the officer appointed by government for that purpose; and it is only in the event of their being approved by him, and the tables of payments and allowances appearing suitable to the justices, that the society is to be confirmed by the latter, and becomes entitled to the privileges conferred by the act in question. These consist in being allowed to invest the funds of the society in government securities at a minimum rate of interest (2½*d.* per cent. per diem), and in the funds of savings' banks. But it is, of course, open to any individuals, not seeking any connection with government, to establish friendly societies on any terms they may think proper." (*Statistics of the British Empire.*)

FRIEZE. (Ital. fregio, *adorned.*) In Architecture, the member in the entablature of an order between the architrave and the cornice. It is always plain in the Tuscan; ornamented with triglyphs and sculpture in the Doric; in the Ionic it is occasionally, in modern or Italian architecture, swelled, in which case it is called a *pulvinated* or *cushioned* frieze; and in the Corinthian and Composite it is variously decorated, according to the taste of the architect.

FRI'GA, or FREYA, in Northern Mythology. *See* Odin.

FRI'GATE, is applied to a ship with one covered gun deck, and carrying more than twenty-eight guns.

FRIGIDA'RIUM. (Lat. frigidus, *cold.*) In ancient Architecture, the apartment in which the cold bath was placed. It is sometimes used to denote the bath itself.

FRI'GID ZONE. The space about either pole of the earth terminated by the parallel of 76½ degrees of latitude. At this parallel the sun at noon, in the middle of winter, is 90 degrees from the zenith; and consequently, were it not for the refraction, would only be visible for an instant in the horizon. Within this parallel the sun continues invisible in winter, and constantly visible in summer, for a shorter or longer space of time, depending on the distance of the place from the pole, where the sun remains for one half of the year above the horizon, and the other half below it. *See* Zone.

FRINGI'LLA. (Lat. fringilla, *a chaffinch.*) A Linnæan genus of Passerine birds, characterised by a broad-based, sharp-pointed, strong, conical bill: now raised to the rank of a family, *Fringillidæ;* including the buntings (*Emberiza*); the cross-bills (*Loxia*); the grosbeaks (*Coccothraustes*); the linnets (*Linaria*); canary-birds (*Canaria*); finches (*Carduelis*); and many exotic subgenera of seed and grain-eating Conirostral birds.

FRITH, or FIRTH (Lat. fretum, *a narrow sea*), is a term chiefly applied to a narrow and deep inlet of the sea upon a river, as the Frith of Forth in Scotland. This term corresponds to the fiord of the Danes and Norwegians, who, in all probability, borrowed it from the English. Both Latin and Teutonic are derived not improbably from the same root, *fahren*, to pass over; whence ferry, ford, furt (Germ.), as in Frankfurt, Erfurt, &c.

FRITT. The materials of glass are first mixed together, and heated, so as to expel water, and induce fusion: the mass thus obtained is called *Fritt.*

FROG. *See* Batrachia and Rana.

FROND. A combination of stem and leaf in one organ, as in *Lemna*, *Marchantia*, and such plants. It is often also misapplied to the leaves of palm-trees and ferns, which differ in no respect from common leaves.

FRONDE, WAR OF THE. That maintained by the malcontent partizans of the parliament in France, under the regency of Louis XIV., against the government of Cardinal Mazarin. The name of Fronde (*sling*) was given to this war in consequence of some incidents of a street quarrel, which have been differently represented. The party opposed to government was called that of the Fronde; and the word Frondeurs has hence acquired in the French language the signification of discontented politicians. Among the best authorities to consult on this period of French history are, Mailly, *Esprit de la Fronde*, 2 vols. Paris, 1772; the well-known *Memoirs of*

Cardinal de Retz; and those of *Guy Joly*, 2 vols. Amst. 1718. See also other Memoirs in *Petitot's General Collection.*

FRONS. In Mammalogy, the region of the cranium between the orbits and the vertex. In Ornithology, the space between the base of the bill and the vertex.

FRO'NTAL BONE. The front bone of the head, which forms the forehead.

FRO'NTIER (Ital. frontiera, Lat. frons), means the boundary of a state, or the territories adjacent to the boundary. The best frontier is the sea; next best, great rivers or mountains, as the Rhine, Rhone, Alps, and Pyrenees. Prussia has the worst frontier of any European state, and will run a great chance of being annihilated on the occurrence of a Continental war.

FRO'NTISPIECE. (Lat. frons, *front*, and inspicio, *I look upon.*) In Architecture, the face or fore front of a house; but more usually applied to the decorated entrance of a building. This term is also used for the ornamental first page of a book, being, as the derivation imports, that part which first meets the eye.

FRONTLET. In Ornithology, the margin of the head behind the bill of birds, generally clothed with rigid bristles.

FROST, in Meteorology, is the freezing or congelation of water or the vapours of the atmosphere by cold. Water begins to freeze when the temperature of the air is such that the mercury in Fahrenheit's thermometer stands at 32°. At this temperature ice begins to appear, unless some circumstance, for example the agitation of the water, prevents its formation. As the cold increases the frost becomes more intense, and liquids which resist the degree of cold required to congeal water at length pass into the solid state. Frost is peculiarly destructive to vegetation. During severe frosts almost all vegetables fall into a state of decay, and even a moderate degree of frost is sufficient to destroy many of the more tender kinds. The injury which vegetables sustain from frost is greatest when it is preceded by a thaw or copious rains; for the plants are then saturated with moisture, which, expanding in bulk as it passes into the solid state, produces the rupture of the vegetable fibres. Fruits are in like manner destroyed by frost. Their watery portion is changed into crystals of ice, which, occupying a greater space than the fluid from which they were produced, burst the small vessels in which they are formed; hence the fruit is deprived of its flavour, and, when thaw takes place, falls into putrefaction.

The *hoar frost* or *white frost*, which appears in the mornings, chiefly in autumn and spring, is merely frozen dew. It is generally the consequence of a sudden clearing up of the weather after rain, when a considerable degree of cold is produced by the rapid evaporation. In our European climates, it usually happens that after a fall of rain the wind shifts into a northern quarter, and the atmosphere suddenly clears up. When this takes place during the night, or early in the morning, a strong radiation of heat from the earth commences, the cooling effect of which is increased by the copious evaporation from the wet surfaces of the plants and the grass. The influence of evaporation on the phenomenon is obvious from this, that the moisture which appears in the form of dew before sunrise is often changed into *rime* or hoar frost on the appearance of that luminary. The reason is, that as the atmosphere begins to be warmed by the sun's rays, the evaporation is accelerated, and consequently the cold at the wet surface of the ground augmented. Hence we see the reason why frosty nights are so much more prejudicial to the tender shoots of plants when they are succeeded by very bright mornings. Hence also hoar frost is formed on grass or plants when the thermometer, placed a few feet above the ground, indicates a temperature three or four degrees above the freezing point.

Various projects have been proposed at different times to avert the disastrous effects of the morning frosts on vegetation in spring; but unfortunately it is only on a very limited scale that any means can be adopted for the purpose. Whatever prevents the formation of dew will protect plants; hence a covering of net or thin gauze will often preserve the blossoms of wall-fruit. But the most effectual means is to check the radiation by screening the plant from the chilling aspect of the clear sky. *See* Dew.

FRUIT, in Botanical language, is the ovarium or the pistillum arrived at maturity; but the term is commonly extended to whatever is combined with the ovarium when it is ripe. It comprehends many kinds of what are commonly called seeds; as those of corn, buckwheat, caraway, parsley, &c.; as well as the succulent inflorescence of the pine-apple, which is a mass of ovaria and envelopes in a consolidated condition.

FRUST, or FRUSTUM. (Lat. frustum, *cut off.*) In Architecture, a piece cut off from a regular figure, as the shaft of a column is a frustum of a paraboloid.

FRU'STUM. In Geometry, the part of a solid next the base, formed by cutting off the top; or it is the part of any solid, as a cone, a pyramid, &c., between two planes, which may be either parallel or inclined to each other. The frustum of a pyramid, when the cutting plane is parallel to the base, is equal to the sum of three pyramids whose bases are,—1st, the lower base or end of the frustum; 2d, the upper base; and 3d, a surface which is a geometrical mean between these two. Hence the solid content of such a frustum, whatever be the figure of the base, is found by this rule:—Add into one sum the area of the two ends and the mean proportional between them, then one third of that sum will be the area of the base of an equal prism having the same altitude as the frustum; and consequently this area multiplied into the altitude gives the solid content of the frustum.

FRU'TEX (Lat. *a shrub*), is a plant whose branches are perennial, and proceed directly from the surface of the earth without any supporting trunk.

FUE'L. (Norm. Fr. fuayl.) Any combustible substance which is used for the production of heat constitutes a species of fuel; and in this extended sense of the term, alcohol, wax, tallow, coal gas, oil, and other inflammable bodies which are occasionally used, especially in the chemical laboratory, as sources of heat as well as light, might be included under it. But the term *fuel* is more properly limited to coal, coke, charcoal, wood, and a few other substances, which are our common *sources of heat*, and as such are burned in grates, stoves, fireplaces, and furnaces of different descriptions.

In this country coal, from its abundance and cheapness, is the commonly employed fuel; but where wood is abundant, or where its value is little more than that of felling it, it is used either in its original state or in the form of charcoal. But whatever substance is used, the ultimate elements of fuel are carbon and hydrogen; and the heat which is evolved by their combustion is derived from their combination at high temperatures with the oxygen of the air: the results or products of this combustion are carbonic acid and water, these escaping into the atmosphere by the flue or chimney generally attached to furnaces and fireplaces.

It is essential to good and profitable fuel that it should be free from moisture; for unless it be dry, much of the heat which it generates is consumed in converting its moisture into vapour: hence the superior value of old, dense, and dry wood, to that which is porous and damp; hence also the greater quantity of heat evolved during the combustion of charcoal as compared with that of wood, for even the driest wood always retains a certain quantity of water; hence also coke gives out more heat than pit coal, partly because it is absolutely dry, and partly because during the combustion or heating of coal, tar, oil, water, and gas are evolved, all of which carry off a certain proportion of the heat in a latent form. A pound of dry wood will, for instance, heat 35 pounds of water from 32° to 212°, and a pound of the same wood in a moist or fresh state will not heat more than 25 pounds from the same to the same temperature; the value, therefore, of different woods for fuel is nearly inversely as their moisture, and this may be roughly ascertained by finding how much a given weight of their shavings loses by drying them at 212°.

Charcoal is itself very hygrometric, and when exposed to air increases in weight to the amount of 10 or 12 per cent. in consequence of the absorption of humidity: a pound of dry charcoal is capable of raising, when properly burned, 73 pounds of water from the freezing to the boiling point.

The different kinds of pit coal give out variable quantities of heat during their combustion; upon an average, one pound of coal should raise 60 pounds of water from the freezing to its boiling point. The heating power of coke as compared with coal is nearly in the ratio of 75 to 69: a pound of good coke will heat from 64 to 66 pounds of water from 32° to 212°; its power, therefore, is about nine tenths that of wood charcoal.

The value of turf and peat as fuel is liable to much variation, and depends partly upon their density, and partly upon their freedom from earthy impurities. A pound of turf will heat about 26 pounds of water from 32° to 212°, and a pound of dense peat about 30 pounds: by compressing and drying peat its value as a fuel is greatly increased.

The following table, by Dr. Ure, shows the quantity of water raised from 32° to 212° by one pound weight of the

Combustible.	Pounds of Water which a Pound can raise from 32° to 212°.	Pounds of Boiling Water evaporated by One Pound.	Weight of Atmospheric Air at 32° required to burn One Pound.
Dry wood	35·00	6·36	5·96
Common wood	26·00	4.72	4·47
Charcoal	73·00	13·27	11·46
Pit coal	60·00	10·90	9·26
Coke	65·00	11·81	11·46
Turf	30·00	5·45	4·60
Coal gas	76·00	13·81	14·58
Oil, wax, or tallow	78·00	14·18	15·00
Alcohol	52·00	9·56	11·60

different combustibles enumerated in the first column; it also shows the number of pounds of boiling water which the same weight of fuel will evaporate, and the quantity of atmospheric air absolutely consumed during combustion. The quantity of air, however, as given in the last column, is much less than would be necessary in practice, where much of the air passes the fuel without coming into contact with it so as to have its oxygen consumed. The heating power also, as represented by this table, can seldom be *practically* attained.

FUE'ROS, is the term by which in Spain the peculiar rights and privileges of certain provinces are distinguished. It corresponds to the old French word *for* or *fors;* and is said to be derived either from the Latin word *forum*, or (what is more probable) from the Spanish *fuera*, which signifies *outside* or *without*, thereby indicating the difference which exists between the administration of the provinces in which the fueros prevail from that of the other constituent parts of the Spanish monarchy. The history of the fueros is lost in their profound antiquity; but there can be little doubt that their origin may be fairly associated with the political existence of the brave Cantabrians, who were never wholly subjugated to the Roman yoke, and who even when partially vanquished still maintained their ancient laws and customs inviolate. Be this as it may, it is well known that from their earliest origin the Basque Provinces enjoyed certain privileges unknown to the rest of the Spanish kingdom, and which, though originally not reduced to writing, and existing like our own common laws of old in the traditions of the country, were mutually and religiously observed both by the monarch and the people. In this state they remained till the year 1235, when, on the accession of Thibault, a French prince, to the crown of Navarre, some misunderstanding having arisen respecting the nature and extent of the fueros, it became necessary to embody them in a written code, which, with some considerable enlargement sanctioned by Charles V., was, down to the period of the last revolution, faithfully recognized by all the monarchs of Spain as the magna charta of the Basque Provinces. Though the immunities of the provinces, Guipozcoa, Alava, Biscay, and Navarre, exhibit considerable difference in detail, their main features are marked by a striking uniformity, the form of government which prevails in each province being essentially republican in all its branches. In the province of Biscay, for instance, which, with a few modifications more or less important, may serve as an example for the other provinces, the royal authority is purely nominal. The only privilege of the crown consists in nominating the corregidor, the highest officer in the state; but even this appointment is subject to the approval of certain members (called *deputation*) of the *junta* or states, in whose assemblies he has a seat and vote. In the junta is vested the chief management of affairs. This assembly forms, with the exception of the American congress, by far the most popularly constituted representative body in modern times, the right of voting being conferred on every man who possesses a domicile within the lordship; and its chief duties consist in administering the affairs of the commonwealth, in collecting the taxes, in providing for the protection and defence of the country, in nominating the official servants of the government, and in forming of itself a court of appeal from the decisions of the corregidor. Of the privileges and immunities of the province itself the following are the principal: — Freedom from paying any imposts but those due from the inhabitants to their own lordship, and which are fixed by themselves, and additionally whatever gratuitous contributions may be deemed necessary to meet the extraordinary emergencies of the state; the enjoyment of the privileges of nobility in the Castilian dominions on merely proving a descent from pure Biscayan blood; exemption from appearing before any tribunal beyond the limits of the lordship; to tolerate no royal intendant or comptroller within the province; to permit no *estanco* or royal monopoly, as in the rest of Spain; exemption from duty on imported merchandise; to have no royal administration, except that of the post-office; to admit no Spanish troops within the territory; to furnish no recruits for the royal army; to defend their territory with their own means and blood; and to visit with summary punishment all who may be convicted of extortion, or of any attempt to injure or even to interfere with the constitution of the province. These details, borrowed chiefly from an able article on this subject in the *Monthly Chronicle* for Nov. 1839, will convey to the reader some idea of the nature and extent of the *fueros*, the maintenance of which formed the sole ground for the sanguinary hostilities which for the last few years devastated the northern provinces of the Spanish territory; — hostilities which have at length happily been put an end to by the formal recognition of all the rights, privileges, and ancient customs of the Basque Provinces, on the part not only of the Spanish government, but also of the Cortes. (For further information on this subject, the reader is referred to a masterly resumé of a work entitled *El Fuero — Privilegios, Franquezas, &c., confirmados por el Rey Don Carlos, nuestros senor, &c.* 1762; commenced in *The Times* of Oct. 14., continued in the same journal 16th Nov. 1839, and ended March 1840.)

FUGA, or FUGUE. (Lat. fuga, *flight.*) In Music, a composition wherein the different parts follow each other, each repeating the subject at a certain interval above or below the preceding part.

FU'GLEMAN, or FLUGELMAN. A non-commissioned officer, appointed to take his place in front of a regiment as a guide to the soldiers in the movements of the drill. The word is derived from Germ. flügel, *a wing.*

FU'LCRA. (Lat. fulcrum, *a prop.*) A term invented by Linnæus to denote a tendril, a prickle, a spine, a hook, or any other process by which plants are enabled to support themselves upon other plants.

FU'LCRUM (Lat.), in Mechanics, is the fixed point about which a lever moves. *See* LEVER.

FU'LGORA. (Lat. fulgor, *an effulgence.*) The generic name of certain singular insects of the order *Homoptera*, and family *Cicadariæ*, which have the fore-part of the head produced in the form of a snout or large hollow receptacle; and the antennæ inserted beneath the eyes, only three-jointed, and terminated by a slender bristle. It is asserted by one naturalist (Mad. Merian), that the frontal projection emits a bright light; but others who have had opportunities of making observations on the "living lantern-fly," as the larger species is called, have not witnessed the exercise of its illuminating powers, if it really possess them.

The *Fulgora lanternaria* is a native of South America; the *Fulgora candelaria* of China. There are many other species included in the Linnæan generic character, but which now form the subgenera *Otiocerus, Lystra, Cixius, Pœciloptera, Issus, Anotia, Delphax, Fulgora proper, &c.*, in the family *Fulgoridæ.*

FULGURA'TION. A term applied by the assayer to the sudden brightening of the fused globule of gold or silver when the last film of oxide of lead or copper leaves its surface.

FU'LICA. (Lat. fuliga; from fuligo, *soot.*) The name of a genus of Wading birds of the family *Macrodactylæ*, now restricted to those which have a strong, moderate-sized, straight, conical, and compressed bill, with a dilated naked plate at the base of the upper mandible: the toes are furnished at the sides with a scalloped membrane; the wings middle-sized. The British species, or common coot (*Fulica atra*), is well known: all its congeners approach more or less to its sooty or blue-black colour.

FU'LLERS' EARTH. A mineral essentially composed of silica and alumina, with about 24 per cent. of water, used in fulling cloth. Like other soft aluminous minerals, it has the property of absorbing grease. It occurs in Hampshire, near Woburn in Bedfordshire, and at Nutfield in Surrey: its exportation was formerly forbidden under severe penalties. In most cases soap is now substituted.

FU'LLING. The art of cleansing, scouring, and pressing stuffs, cloths, stockings, &c., to render them stronger, firmer, and closer; it is also called *milling*, because these cloths, &c. are in fact scoured by a water mill. (See *Ure's Dictionary of Arts, &c.*)

F'ULMINATES. (Lat. fulmen, *a thunderbolt.*) Compounds of the fulminic acid with various bases, all more or less possessed of the property of exploding or detonating by heat or friction. The fulminates of silver and mercury (or fulminating silver and mercury) are objects of manufacturing interest; the former being used in detonating *bonbons*, and the latter more largely and importantly as a priming for the percussion caps of gun locks.

FU'LMINATING POWDER. A compound of three parts of nitre, two of purified pearlash, and one of flowers of sulphur, carefully mixed and dried before the fire: about 20 grains of this powder heated upon an iron plate over a slow fire become brown and pasty; a blue flame then appears upon it, and immediately after the whole explodes with a stunning report.

FULMINA'TION, used synonymously in a general sense with *denunciation;* but applied more peculiarly to the excommunications or anathemas pronounced by the papal see.

FULMI'NIC ACID. An acid composed of 2 equivalents of cyanogen = 52, and 2 of oxygen = 16. corresponding therefore in ultimate composition with the *cyanic acid.* In combination with the oxide of silver and oxide of mercury, this acid constitutes fulminating silver and fulminating mercury.

FUMARIA'CEÆ. (Fumaria, one of the genera.) A natural order of herbaceous Exogens, inhabiting all temperate climates, and related to *Papaveraceæ* so nearly as to be incorporated with them by some writers. Their sensible properties are not of any value; a few are objects of cultivation for their beauty.

FUMIGA'TION. (Lat. fumigo.) The diffusion of certain vapours through the air, for the purpose of destroying contagion and infection: goods are also fumi-

gated for the same purpose. Acid vapours have frequently been used for this purpose; there are, however, very few which are at all effectual, and some of them, such as vinegar, only serve to cover bad smells without destroying noxious effluvia. There is no substance so certain in its effects as *chlorine;* and it is cheap, and easily obtained either from muriatic acid and black oxide of manganese, or from a mixture of salt, sulphuric acid, and black oxide. In inhabited rooms it requires to be cautiously used, in consequence of its bad effects upon the respiratory organs; but even here it may be so extensively diffused as to be effective in destroying noxious matters, without serious injury to persons who breathe the atmosphere. When a room can be shut up it may be freely used, and it should be generated in saucers placed in different parts of the apartment (if a large one); and not upon the ground, but upon shelves high up in the room, for chlorine being heavier than air is thus more quickly and rapidly diffused. Infected clothes and furniture may at the same time be subjected to its action. Of all common diseases, the scarlet fever is that which appears to require the most scrupulous attention to careful fumigation.

FU′NCTION, in Analysis, signifies any mathematical expression considered with reference to its form, and not to the value which it receives by giving particular values to the symbols contained in it. Thus $a + x$ and $a^2 + x^2$ are both functions of x, though of different forms. In whatever manner an expression may be compounded of constant and variable quantities, it is always called a function of the variable quantities only, because it is only with reference to the manner in which the variables enter into the expression that it is necessary to consider the function. Thus the above expressions, as well as the following, $a + \log. x$, $b + \sin. p\,x$, c^x, are all functions of x, the quantities a, b, p, c, being constant, and independent of x. The *calculus* of functions may be regarded as standing in the same relation to algebra that algebra occupies with regard to common arithmetic. The definite abstract numbers about which arithmetic is concerned are in algebra laid aside for symbols of general number, thus enabling us to express a definite operation performed on an indefinite number. In the calculus of functions the generalization is carried a step farther; the definite character of the operation is dropped, and indefinite symbols of operation are used, which may be unknown, but determinable by certain conditions; or arbitrary, or conventionally definite, to denote particular operations. (See "Calculus of Functions," in the *Ency. Metrop.*, by Mr. De Morgan; also *Babbage's Elementary Treatise on the Calculus of Functions;* Lagrange, *Théorie des Fonctions Analytiques;* Cauchy, *Cours d'Analyse* and *Elémens du Calcul Infin.; Peacock's Algebra*, &c.)

FUNDAMENTAL BASS. In Music, the lowest note or root of a chord, which is found by inverting its notes so as to set them in thirds above such root.

FUNDS, PUBLIC. The name given to the public funded debt due by government.

The practice of borrowing money in order to defray a part of the war expenditure began, in this country, in the reign of William III. In the infancy of the practice it was customary to borrow upon the security of some tax, or portion of a tax, set apart as a fund for discharging the principal and interest of the sum borrowed. This discharge was, however, very rarely effected. The public exigencies still continuing, the loans were, in most cases, either continued, or the taxes were again mortgaged for fresh ones. At length the practice of borrowing for a fixed period, or, as it is commonly termed, upon *terminable* annuities, was almost entirely abandoned; and most loans were made upon *interminable* annuities, or until such time as it might be convenient for government to pay off the principal.

In the beginning of the funding system, the term fund meant the taxes or funds appropriated to the discharge of the principal and interest of loans; those who held government securities and sold them to others selling, of course, a corresponding claim upon some fund. But after the debt began to grow large, and the practice of borrowing upon interminable annuities had been introduced, the meaning attached to the term fund was gradually changed; and instead of signifying the security upon which loans were advanced, it has, for a long time, signified the principal of the loans themselves.

Owing partly, perhaps, to the scarcity of disposable capital at the time, but far more to the supposed insecurity of the revolutionary establishment, the rate of interest paid by government in the early part of the funding system was, comparatively, high. But as the country became richer, and the confidence of the public in the stability of government was increased, ministers were enabled to take measures for reducing the interest, first in 1716, and again in 1749.

During the reigns of William III. and Anne, the interest stipulated for loans was very various. But in the reign of George II. a different practice was adopted. Instead of varying the interest upon the loan according to the state of the money market at the time, the rate of interest was generally fixed at *three* or *three and a half* per cent.; the necessary variation being made in the principal funded. Thus, suppose government were anxious to borrow, that they preferred borrowing in a 3 per cent. stock, and they could not negotiate a loan for less than 4½ per cent., they effected their object by giving the lender, in return for every 100*l.* advanced, 150*l.* 3 per cent. stock; that is, they bound the country to pay him or his assignees 4*l.* 10*s.* a year in all time to come, or otherwise to extinguish the debt by a payment of 150*l.* In consequence of the prevalence of this practice, the principal of the debt now existing amounts to nearly *two fifths* more than the sum actually advanced by the lenders.

Some advantages are, however, derivable, or supposed to be derivable, from this system. It renders the management of the debt, and its transfer, more simple and commodious than it would have been had it consisted of a great number of funds bearing different rates of interest: and it is contended that the greater field for speculation afforded to the dealers in stocks bearing a low rate of interest has enabled government to borrow, by funding additional capitals, for a considerably less payment on account of interest than would have been necessary had no such increase of capital been made. *See* NATIONAL DEBT.

FU′NERAL (Lat. funus), may be defined generally as the last rites performed to a deceased person, of whatever nature they may be, whether of interment, burning, embalming, &c. Among the ancients ceremonies of this nature were accompanied by processions, and gladiatorial combats, called *funeral games;* and were usually followed, particularly where the deceased was of high rank or otherwise distinguished, by a discourse, or funeral oration, pronounced in his praise. (See SEPULTURE, RITES OF.)

FU′NGI. A large natural order of plants of a very low organization, consisting chiefly of cellular tissue, sometimes intermixed with flocculent matter, and very rarely with spiral vessels. They inhabit dead and decaying organic bodies, and are also a common pest to living plants, upon which they prey in the same manner as vermin and intestinal worms upon animals. A vast number of species are described by writers upon fungi, called mycologists; and they are often of great importance to man either for their use or their mischievous qualities. The common mushroom, the truffle, and morel, are delicacies well known at table: ergot is valuable in obstetric practice as a uterine stimulant; very many are dangerous poisons. Blight, mildew, rust, brand, &c., are diseases caused by the ravages of microscopic fungi; and finally the destructive effects of dry rot are owing to the attacks of *Merulius lachrymans* and many other species, some of which are microscopic. The best general work on Fungi is *Fries's Systema Mycologicum.* Numerous species are figured in the works of Greville, Bulliard, Sowerby, Corda, and Nees von Esenbeck.

FUNGI′COLA. (Lat. fungus, *a mushroom*, and colo, *to inhabit.*) The name of a family of Coleopterans, comprehending those which are found on mushrooms.

FUNGI′LLIFO′RMIS, a Latin term signifying *mushroom-headed*, is applied to any bodies having a short thick figure, one end of which is much more dilated than another.

FU′NGIN. The fleshy part of mushrooms purified by digestion in hot water.

FU′NGUS, in Surgery, is a term applied to the too luxuriant formation of flesh about an ulcer, or what is commonly called *proud flesh.*

FUNI′CULAR MACHINE. (Lat. funis, *a rope.*) In Mechanics, if a body fixed to two or more ropes is sustained by powers which act by means of those ropes, the assemblage is called the *funicular machine*, or *rope machine.* If a rope is stretched horizontally between two points, its own weight alone will prevent it from becoming perfectly straight, whatever force be employed in stretching it; and a very small force applied at its middle point, at right angles to its direction, will be sufficient to overcome a very great resistance at the points to which its extremities are attached. In this manner a very small force may be made to raise a very great weight to a minute height. This method of applying force is familiar to seamen, who frequently have recourse to it in bracing their sails.

FUNI′CULUS. A prolongation of the placenta in the shape of a cord, to which the ovules are attached.

FU′NNEL. (Lat. infundibulum.) In Architecture, the upper part of a chimney. In common life, it is a trumpet-mouthed utensil, with a pipe fixed to the apex for the purpose of conveying liquors into a vessel without spilling them.

FU′NNEL-SHAPED. In Botany: used in describing the general form of a calyx, corolla, or other organ, the tube of which is like a funnel or inverted cone; that is, narrowest at the base and widest at the orifice.

FUR. (Fr. fourrure.) The coated skins of wild animals, especially of those of high northern latitudes; such as the wolf, bear, beaver, &c. The hair or fur is cleansed, and the skin is generally slightly tanned or tawed. The most valuable furs, such as ermine and sable, come chiefly

from Russia. When unprepared, or merely dried, the fur skins go under the name of *peltry*.

FURFURA'CEOUS. (Lat. furfur, *bran*.) A term applied to certain eruptions in which the cuticle peels off in scales: also to a branlike sediment which is sometimes observed in the urine.

FU'RIES (Furiæ), in Mythology, called by the Greeks Erinnyes ('Ερίννυες) and Eumenides (Εὐμενίδες), were the avenging deities, who punished gods and men for their transgressions against those whom they were bound to esteem and reverence. Their number was not fixed, though sometimes they were considered to be three sisters. The Athenians, who, according to Plutarch (Soton), were particularly addicted to this sort of *euphemism*, called them also Σεμναι Θεαι, the *venerable goddesses*, their true names being considered ominous. By this name they were mentioned in the oaths taken at the Areopagus.

FURL. In Navigation, to roll the sail up and confine it closely to the yard; the sail being gathered up by the men on the yard, the leech or edge is passed along the yard to the middle or *bunt*, where the body of the sail, the foot and clews, are collected. In this way the sails of a man of war are removed nearly out of view in an almost incredibly short space of time.

FU'RLONG. An English measure of length, containing the eighth part of a mile.

FU'RLOUGH, in Military language, signifies the permission granted to an officer or soldier to absent himself for a given time from military duty.

FU'RNACE. (Lat. fornax.) An apparatus wherein is placed a cavity to contain combustible matter, which in various ways is supplied with air to facilitate its combustion. The two classes into which furnaces are divided are air or wind furnaces, and blast furnaces. In the former the air is conducted through the fire by the draught of a funnel or chimney which communicates with it; in the latter, the action of bellows or some other pneumatic apparatus supplies the air. The word furnace has generally, however, a more circumscribed application; being applied usually to an apparatus for the fusion of metals, or to that used in a chemical laboratory.

FU'RNITURE. In Printing, the materials used to extend pages of type to their proper length; also to separate them, when imposed, to a just distance from each other, so that when the sheet is printed and folded the margin shall be regular and uniform. (*See* IMPOSING.) It consists of pieces of oak wood planed up to specific thicknesses, and to about half an inch high; sidesticks and footsticks, which are placed at the outside of the pages, and made thinner at one end than the other, to allow the quoin to secure them more effectually; and quoins or wedges, usually made of beech wood, with which the pages are wedged up in a chase. *See* CHASE.

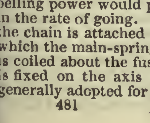
FU'RNITURE. (Fr. fournir, *to furnish*.) In Architecture, the visible brasswork of locks, knobs to doors, window shutters, and the like.

FU'RRING. (Fr. fourrer, *to thrust in*.) In Architecture, the small slips nailed on joists or rafters, where some parts of them are lower than others, or where the surface is not regular, so as to bring the boarding they are to receive into the same planes.

FURU'NCULUS. (Lat. furo, *I rage*.) A boil; an inflammatory tumour, which generally has a central core, and appears in full and healthy habits. Where boils prevail in delicate constitutions, they generally indicate a cachectic state, which is often corrected by a course of sarsaparilla.

FURZE. A prickly bush, found abundantly in exposed heaths in England and the more southern countries of Europe, from which it is by some supposed to have been introduced; a conjecture rendered probable by its not being able to bear the more rigorous of our winters. Its preference for sterile soil has caused it to be extensively used for fences in such land, as a cover for game and a shelter for young plantations. Its young and tenderer shoots are browsed upon by sheep and cattle. Botanists call it *Ulex Europæus*, and class it with the Leguminous order.

FUSE'E. In Watch-work, that part of the machinery about which the chain is wound, and which is immediately acted upon by the main-spring. The use of the fusee is to equalize the action of the spring. In proportion as the spring becomes unwound, its effort continually relaxes; so that if the first wheel were attached to the barrel, as is often the case in common watches, the inequality of the impelling power would produce a corresponding inequality in the rate of going. In order to correct this, one end of the chain is attached to and wound round the barrel in which the main-spring is contained; while the other end is coiled about the fusee, which has a conical shape, and is fixed on the axis of the first wheel. The principle generally adopted for determining the figure of the fusee



is, that its radius, at any point to which the chain is a tangent, should be inversely as the tension of the chain in that position. Within certain limits this is nearly true; and if we assume with Hooke that the force of a spring is proportional to the distance to which it is drawn from the position of rest, and also lay aside all consideration of the length of the chain wrapt about the fusee, it would be easy to show that the fusee should be the solid generated by the revolution of the equilateral hyperbola about its asymptote. This conclusion is, however, by no means correct; but though the subject has been treated by several eminent mathematicians, very little practical advantage has been derived from the theoretical investigations. In fact, a moderate approximation to the true figure (whatever that may be) is all that can be attained in practice, and all that is necessary.

FU'SIBLE METAL. An alloy of eight parts of bismuth, five of lead, and three of tin. It liquefies at a temperature below 212°.

FU'SIBLE SALT OF URINE. A name by which the old chemists designated the *ammonio-phosphate of soda*, obtained by the evaporation of urine.

FUSIL (Fr. fusee), in Heraldry, is a bearing of a rhomboidal figure more slender than the lozenge; its upper and lower angles being more acute than the two middle ones.

FU'SIL. A light musket nearly similar to a carabine, but in general more neatly finished. The fusil was originally used by officers attached to light companies; and in the British army it has given its name to several regiments called the *fusiliers*. The bore is usually calculated for balls of eighteen to the pound; and the length of the barrel is from thirty-four to thirty-eight inches.

FUST. The same as *Frust*, which see.

FU'STIAN. (Fr. fustaine.) A thick twilled cotton, of which velveteen, corduroy, and thickset are varieties. (*See* VELVET.) Fustian is generally dyed of a deep olive or lead colour.

FUSTIAN, in Criticism, is applied to writings remarkable for a forced elevation of style, or for an exaggerated or unnatural use of metaphors or other rhetorical figures.

FU'STIC. A yellow dye stuff. There are two kinds of fustic occasionally used by dyers. *Old fustic* is the wood of a large tree, the *Morus tinctoria*, which grows abundantly in many parts of the West Indies and America; it gives a dingy yellow dye, and is chiefly useful in the production of compound colours. *Young fustic* is the *Rhus cotinus*, or Venice sumach, a shrub growing in Italy and the south of France; it gives a greenish-yellow dye, and is also used as an accessory material.

FU'TTOCK PLATES. Flat iron bars or plates, receiving at one end the lower dead-eye of the topmast rigging, and at the other the futtock shroud.

FU'TTOCKS. In Nautical language, the timbers between the floor timbers and the top timbers.

G.

G. The seventh letter of the English alphabet, but the third in those of all the Oriental languages, and also of the Greek. The form of our G is borrowed from the Roman alphabet. G, in English, has two sounds: before *a*, *o*, and *u*, and occasionally before *i* and *e*, it is the medial letter of the guttural order; the other sound, which it possesses only before *e* and *i*, is one of the medials of the sibilant series. The guttural G is liable to a variety of changes in different dialects and languages. (See *Penny Cyclo.*) G, as a Roman abbreviature, is used for gratis, gens, gaudium, &c. G. V. signifies genio urbis, G. L. genio loci, and G. P. R. gloria populi Romani. As a numeral it denoted 400,—

G quadringentos demonstrativa tenebit.

On the French coins G indicates the city of Poictiers; and in chronology it is the seventh Dominical letter. G, in music, is the fifth note or degree of the diatonic scale, corresponding to the sol of the French and Italians. It is used also to designate the treble clef.

GABE'LLE. (Probably derived, through some unknown inflexion, from the Teutonic word geben, *to give*.) Any impost laid on commodities was originally thus termed in France; as, gabelle de vin, de draps, &c.: but the word acquired in the course of time the peculiar signification of a duty on salt, which is meant when the word "gabelle" is used simply. The Gabelle was first established in the early part of the 14th century, during the reign of Philip de Valois, and with a brief interruption of five years, from 1340 to 1345, continued to be levied down to the reign of Louis XVI., at which time the revenue it produced was estimated at 38 millions of francs. The distribution of this tax was most capricious and arbitrary, some provinces having been altogether exempt from, some more and others less subject to, its operation: and it may safely be affirmed that the gabelle was one of the greatest curses imposed on France previously to the

Revolution. (See *Com. Dict.*, art. "Salt;" art. "Taxation," *Supp. Encyc. Brit.*)

GA'BIONS, in Fortification, are baskets made of twigs, which, being filled with earth, are used as a screen from the enemy's fire.

GA'BLE. (Brit. from gavel.) In Architecture, the vertical triangular piece of wall at the end of a roof, from the level of the eaves to the summit.

GA'DFLY. *See* Œstrum.

GA'DOIDS, *Gadoidæ.* (Gr. γαδος, *a fish.*) A family of soft-finned fishes, which belong to the section *Subbrachians*, or those which have the ventral fins below or in advance of the pectorals, and of which the cod-fish (*Gadus morrhua*, Linn.) may be regarded as the type.

The general character of the Gadoid family is as follows:—Body moderately elongated, sub-compressed, and covered with soft and very numerous scales; head smooth; jaws and front of the vomer armed with pointed, unequal, moderate, or small teeth, disposed in several rows, like a rasp; gill-openings large, and with seven rays; most of the species with two or three dorsal and one or two anal fins; stomach strong and capacious; cœcal appendages very numerous; air-bladder large, with strong parietes, often dentated laterally. The greater number of the cod tribe inhabit the seas of cold or temperate latitudes; their flesh is white and well-flavoured; they are most prolific, and constitute the most important subject of fisheries. The great sand-bank of Newfoundland is the most famous of the cod-fisheries: here 100,000,000 pounds weight have been taken by the British alone in one year.

GA'DOLINI'TE. A mineral found almost exclusively in Sweden, containing yttria and oxide of cerium; named in honour of Dr. Gadolin, who discovered yttria.

GAFF. The boom or yard extending the upper edge of what are called *fore* and *aft* sails. The gaff turns round the mast, against which it rests in a circular opening (called the *jaws*) as an axis. It is supported by two independent ropes; the *throat halliards* at the mast, and the *peak halliards* at the outer end. It is steadied, when the sail is not set, by ropes at the extremity called *vangs*.

GAGE, or GAUGE. (Ang. S. gæggian, *to bind or confine.*) In Architecture, the length of a slate or tile below the lap; also the measure to which any substance is confined. Plasterers use the word to signify the greater or less quantity of plaster of Paris used with the common plaster to accelerate its setting.

Gage. In Physics, an instrument or apparatus for measuring the state of a phenomenon. *Gage of the air pump* is merely a barometer communicating with the inside of the receiver, which marks, in the usual manner, the pressure of the air within the receiver by the height of the equiponderant column of mercury, and consequently shows the degree to which the air is rarefied. A short barometer may be employed for this purpose; but in this case it will not be affected till the rarefaction of the air has been carried so far as to correspond with the length of the tube. An instrument for the same purpose, but on a different principle, was invented by Smeaton, and from its form called the *pear-gage*. It is a vessel suspended in the receiver, and exhausted to the same degree; but when the rarefaction is carried as far as intended, the open orifice of the gage is let down into a vessel containing mercury, which, on the readmission of the air, is forced up into the pear, and the degree of rarefaction is judged of by the quantity of mercury introduced. The idea is ingenious; but the indications given by this instrument are not correct. For *wind-gage*, see Anemometer; *water-gage*, see Hydrometer.

GAILLARDE. (Ital.) The name of a lively dance peculiar to Italy, and supposed to have been practised by the ancient Romans, whence it is sometimes designated Romanesque.

GALA'CTOPOIE'TIC. (Gr. γαλα, *milk*, and ποιεω, *I make.*) A term applied by some medical writers to diet and medicine supposed to promote the secretion of milk.

GALA'GO. *See* Otolicnus.

GALA'NGAL. A dried root brought from China; it has an aromatic smell, and a pungent bitter flavour, and was formerly used in medicine. The greater galangal is the produce of the *Kampferia galanga*, and the lesser of the *Maranta galanga*.

GALATHÆ'A. A genus of long-tailed (*macrourous*) Crustacea, including some very beautiful species (*Gal. rugosa, strigosa, et squamifera*), occasionally found on the British coasts. The true *Galathæa* have the thorax oblong or ovoid, the median antennæ produced, and the pincers elongated. This term is derived from the celebrated nymph of that name.

GA'LAXY, or MILKY WAY. (Gr. γαλα, *milk.*) In Astronomy, "that great luminous band which stretches every evening all across the sky, from horizon to horizon, and which forms a zone completely encircling the whole sphere, almost in a great circle. At one part it sends off a kind of branch, which unites again with the main body, after remaining distinct for about 150 degrees. This remarkable belt has maintained from the earliest ages the same relative situation among the stars; and when examined through powerful telescopes is found to consist entirely of stars, scattered by millions, like glittering dust, on the black ground of the general heavens." (*Herschel's Astronomy; Cabinet Cyclopedia.*) The phenomena of the milky way, says the same illustrious authority, "agree with the supposition that the stars of our firmament, instead of being scattered in all directions indifferently through space, form a stratum, of which the thickness is small in comparison with its length and breadth, and in which the earth occupies a place somewhere about the middle of its thickness, and near the point where it subdivides into two principal laminæ, inclined at a small angle to each other. For it is certain that to an eye thus situated, the apparent density of the stars, supposing them pretty equally scattered through the space they occupy, would be least in a direction of the visual ray perpendicular to the lamina, and greatest in that of its breadth; increasing rapidly in passing from the one direction to the other, just as we see a slight haze in the atmosphere thickening into a decided fog bank near the horizon by the rapid increase of the mere length of the visual ray. Accordingly such is the view of the construction of the starry firmament taken by Sir William Herschel, whose powerful telescopes have effected a complete analysis of this wonderful zone, and demonstrated the fact of its consisting entirely of stars." (P. 376.) *See* Star.

GA'LBANUM. A slightly fetid gum-resin, produced by the *Galbanum officinale*. It is imported from Turkey and the East Indies for medical use, but is a drug of little importance.

GA'LBULA. (Lat. the name of a bird in Martius.) A genus of Scansorial birds closely allied to the kingfishers by their elongated sharp-pointed beak, the upper ridge of which is angular; and by their short feet, the anterior toes of which are almost wholly united: these toes, however, are not precisely the same as those of the kingfishers. The plumage of the species of *Galbula*, which are called by the French "jacamars," is not so smooth as that of the kingfishers, and always has a metallic lustre. They are solitary birds, that live in wet forests, feed on insects, and build on low bushes.

GA'LBULUS. In Botany, a term invented by Gærtner, to denote a form of fruit similar to a cone, excepting that the galbulus is round, and has the heads of the carpels much enlarged. Example — the fruit of the juniper.

GA'LEA, in Antiquity, was the headpiece or helmet used in battle by the Roman soldiers.

Jam galeam Pallas et ægida
Currusque et rabiem parat.

The *galea* was used for the same defensive purposes as the *cassis;* but differed from it in this, that while the cassis was of *metal*, the galea was originally of *hides*. It was too heavy for general use; hence each army was attended by *galearii*, a species of military domestics, whose duty it was to carry the galeæ of the soldiers.

GALE'NA. (Gr. γαλεω, *I shine.*) Native sulphuret of lead.

GA'LENISTS. In Ecclesiastical History, a subdivision of the sect called Waterlandians in the 17th century. (*Mosheim*, Transl., vol. v. 496.) In Medical History the followers of Galen were so termed, in opposition to the practitioners of the chemical school.

GALE OF WIND. The sea term for a continued storm of wind: the lowest degree is the fresh gale, the next a strong gale, and the next a heavy or hard gale.

GA'LEOPITHE'CUS. (Gr. γαλεος, *a weasle*, πιθηκος, *an ape.*) A genus of Insectivorous Mammalia, having the bones of the arm and leg, but not those of the digits, excessively elongated, and supporting extensive lateral folds of skin serviceable as a parachute, but not as organs of flight. The species are restricted to the great islands of the Indian archipelago; their inferior incisors are remarkable for their complex form, like the teeth of a comb.

GALERU'CA. (Lat. galerus, *a cap or tuft.*) A genus of Tetramerous Coleoptera, now the type of an extensive family (*Galerucidæ*), including amongst other subgenera the noxious turnip flies (*Haltica*). All the *Galerucidæ* are vegetable-feeders, both in their larva and perfect state. There are about a dozen known British species of *Galeruca* proper, which are small, and generally dark or dull-coloured beetles.

GALIA'CEÆ. (Galium, one of the genera.) A natural order of herbaceous Exogens, inhabiting the cooler parts of the world. They are distinguished from *Cinchonaceæ* by their square stems and verticillate leaves without stipules. The *Rubia tinctoria* yields madder, and some of the other species produce a similar colouring substance. The torrefied grains of *Galium* are said to be a good substitute for coffee, and the flowers of *Galium verum* are used to curdle milk.

GALL. *See* Bile.

GALL BLA'DDER. An oblong membranous recep-

tacle attached to the under part of the liver. It retains the bile which regurgitates from the hepatic duct, and sends it through the cistic duct, which proceeds from its neck into the *ductus communis choledochus*, and thence into the duodenum.

GA'LLEON. Certain Spanish treasure ships with three or four decks, formerly employed in communicating with Peru.

GA'LLERY. In the Fine Arts, a term applied to a collection of works in painting or sculpture. The earliest gallery of which there is any record was that of Verres. It is described by Cicero, and was rich in pictures as well as sculpture. In Europe, at the present day, the gallery of the Louvre, though much reduced in 1815 by the restoration of many works of art which conquest had enabled the French to acquire, is the finest in Europe, if taken as a whole. That founded at Florence by Cosmo II. long enjoyed the first rank, but must be now considered secondary to the French collection. The other principal galleries of Europe are those at Munich, Dresden, Berlin, and, though last not least both in size and importance, that of the Vatican at Rome; which, however, is more generally called the Museum of the Vatican. The building for the reception of the National Gallery in London is wholly unworthy of the nation and of the fine situation which it occupies. The collection of pictures in this gallery is small, but some of them are of rare and unrivalled excellence. The gallery of antiques at the British Museum is, in many respects, matchless. The galleries of the Duke of Sutherland, Lord F. Egerton, Mr. Hope, and other private individuals, contain many very fine pictures.

GA'LLERY. In Fortification, a covered passage across the ditch of a fortified town. In Mining, *gallery* is a narrow passage from one part of the mine to another.

G'ALLEY. (Fr. galère.) A low-built vessel propelled by sails and oars, either on a single tier, or on tiers of benches one above the other. The war vessels of antiquity were all galleys. Among the Greeks those chiefly mentioned are the pentecontori, which appear to have had fifty oars disposed in a single tier; and the trieres (Lat. triremes), vessels with three banks of oars, concerning the disposition of which much controversy has taken place. It is commonly supposed that a trireme had three banks of oars one above the other; but this is rendered improbable by the circumstance of Pliny making mention of galleys having thirty, forty, and even fifty banks of oars, for it seems hardly credible that so many could have been arranged directly above each other. Some have suggested that the rows of oars in the trireme were disposed, not horizontally, but obliquely; in which case an increase in the number of banks of oars would augment the length, and probably the height would be increased in proportion. (See *Meibomius*, *De Fabrica veterum Triremium*.)

Galleys were likewise chiefly employed by the maritime nations of the middle ages in the Mediterranean. Their use in naval war hardly ceased until the end of the 17th century: and the Venetian republic, down to the period of its extinction, always maintained a number of war galleys. The Venetian galleys had a single tier only, and all modern galleys followed the same construction. These were formidable vessels in a calm, but unfit for a sea, and accordingly found chiefly in the Mediterranean. The Venetians had also a large high-pooped sort of galley called galeazza, whence the word galleass and galliott in old English writers.

The *Deal galley* is a long narrow boat used by the Deal boatmen, and managed on the most hazardous occasions in saving the crew of stranded vessels with consummate skill; it is also used by smugglers on account of its velocity. The *galley* is also the kitchen of a ship.

The punishment of the *galleys*, *i. e.* the employment of condemned criminals in the toilsome employment of rowing them, is said to have originated under the Greek empire; as well as the name Γαλεαροι, or galley slaves—in French galériens. It was used by all the nations bordering on the Mediterranean. In France, under the old jurisprudence, the punishment of the galleys was the severest after that of death. About the end of the reign of Louis XIV., when galleys themselves began to be disused, the galley slaves were employed in hospitals, public works, &c.; and the name of the punishment was changed by the constituent assembly (1798) to *travaux forcés*, compulsory labour, whence the word *forçat* for a criminal so condemned. Under the code of the empire the punishment was accompanied with forfeiture of property, infamy, and branding. By an alteration of the law effected in 1832, the brand was abolished; and the criminals, who had hitherto been intermingled in the three penal fortresses (Toulon, Rochefort, and Brest), were classified. Toulon is now appropriated to those condemned for 10 years and under; Brest, to those from 10 to 20; Rochefort, to the condemned for life. The name *Bagne*, which is applied in France to prisons in which those condemned to compulsory labour are confined, is derived from the famous Bagnio prison at Constantinople, so called on account of some baths situated there. The principal crimes now punished in this manner by the French law are — some acts of violence against the government or public law; coining and forgery; assaults followed by death on legal officers; murder, unless under such aggravated circumstances as are punished by death; cutting and maiming; rape, abduction, burglary, highway robbery, burning of insulated buildings, threatening letters, perjury, &c.

GA'LLI. The priests of Cybele were so named at Rome from the country (Galatia or Gallo-Græcia) in which Pessinus, the head quarters of her worship, was situated: also termed Curetes, Corybantes, and Idæi Dactyli. Cybele, the mother of the gods, was introduced to Rome from Asia on the occasion of a pestilence by the advice of the Sybilline oracles (*Liv.* 29. c. 14.), and her worship became in time one of the most popular in the city. Her priests were eunuchs, of which Lucretius (lib. ii.) gives the alleged reason. They are described as the vilest of mankind by the Roman satirists, yet they had extraordinary power over the vulgar. Juvenal describes them among the low companions of his debauched consul Damasippus: —

Et resupinati cessantia tympana Galli.

GA'LLIC ACID. An acid obtained from galls and several other vegetable astringents. Its ultimate components are 7 *car.* + 3 *h.* + 5 *o.*; its equivalent number is 85.

GA'LLICAN CHURCH. The distinctive title of the Roman Catholic church in France, which maintains a certain degree of independence in respect of the Romish see. The liberties of the Gallican church, first asserted in the Pragmatic Sanction (1438), were defined and confirmed in the Quatuor Propositiones Cleri Gallicani, promulgated in 1682. The occasion of this declaration was a dispute between Louis XIV. and Pope Innocent XI. concerning the right long practised by the French kings of occupying in their own persons the inferior preferments of a diocese which lapsed during the vacancy of the see. It was then determined by an assembly of the French clergy, that the pope has no temporal, but only spiritual rights, as the vicegerent of Christ; that even these are limited by canons and councils; and that the decrees of the holy see are subject to reversal upon the decision of the clergy in general. (See the *Declaration of the French Clergy concerning Ecclesiastical Power*, drawn up by the famous Bossuet, bishop of Meaux, in the assembly convoked by Louis XIV. in 1682.) While, however, it asserts this liberty in speculative points, the Gallican church does not differ from the Romish in any points of faith or ceremonial observances. It was upon the basis of these liberties that the concordat was founded by which the Catholic religion was re-established in France in 1801; and they continue to be maintained upon their original footing, now that the church is no longer connected with the state. It has always been the object of the Jesuits to bring the French church into more deferential submission to the Romish see; and at the present day the party among the clergy who desire this consummation is said to be on the increase. The controversy on this subject was carried on in the last century between the two classes called Cismontane and Tramontane divines. The new Gallican church of the Abbé Chatel, founded at Paris in 1831, seems not to have met with much success. The abbé styles himself primate of it. It denies the infallibility of the pope and of councils, rejects the celibacy of priests, leaves confession voluntary, and performs service in the mother tongue. In all these respects its doctrines approach those of the church of England. (See the *Profession de Foi de l'Eglise Catholique Française*, Par. 1831.)

GA'LLICISM. Literally, a phrase or construction peculiar to the French language, but used generally to denote such phrases or modes of speech in English as are formed after the French idiom.

GALLI'COLA. (Lat. galla, *a gall*, colo, *I inhabit.*) The name of a family of Pupiparous Hymenopterans, including those of which the larvæ inhabit the galls or vegetable excrescences caused by the perforation and oviposition of the parent insect.

GA'LLINA'CEANS, *Gallinacea.* (Lat. gallus, *a cock.*) *See* RASORES.

GALL-INSECTS, *Gall-insecta.* The name of a family of Hemipterans, comprehending those the females of which, towards the period of oviposition, assume a globular form, analogous to the galls caused by the *gallicoles.*

GA'LLINULE, or WATER-HEN. The type of the subgenus *Gallinula*, now dismembered from the *Fulica* of Linnæus, which term is restricted in modern systems of ornithology to the Coots proper.

GA'LLIOTT. A strong and cumbrous vessel used by the Dutch, having a main and mizen mast, which is often close aft.

GALL NUTS. Excrescences produced by the *cynips*, a small insect which deposits its eggs in the tender shoots of the *Quercus infectoria*, a species of oak abundant in Asia Minor. When the maggot is hatched it produces

a morbid excrescence of the surrounding parts, and ultimately eats its way out of the nidus thus formed. The best galls are imported from Aleppo and Smyrna; their principal ingredients are tan and gallic acid. The infusion of galls affords a dense white precipitate in solution of jelly, and a black precipitate with the persalts of iron. The latter property leads to the use of galls in the manufacture of ink and of black dye; they are also used as an astringent in medicine.

GALL OF GLASS. The salts and other impurities which float upon the fused materials for the manufacture of glass, and which is skimmed off. It is also called *sandiver*.

GA'LLON. An English measure of capacity. By act of parliament the imperial gallon is to contain 10 lbs. avoirdupois of distilled water, weighed at the temperature of 62° of Fahrenheit, and the barometer standing at 30 inches. This is equivalent to 277·274 cubic inches. The old English gallon, wine measure, contained 231 cubic inches; beer measure, 282 cubic inches. *See* MEASURES.

GA'LLOPER. In Artillery, the carriage on which the very small guns are conveyed.

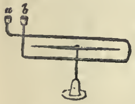
GALLS. Local affections or diseases of plants, caused by the puncture of insects. They are produced by an excessive deposition of cellular tissue, and are of no consequence to the general health of the individual subject to them.

GA'LL-STONES. Concretions occasionally found in the gall bladder and biliary ducts. They consist either of a peculiar fatty matter called *cholesterine*, or of inspissated bile, or of mixtures of the two. The gall-stones of the ox generally contain a peculiar yellow colouring matter, which is much valued by painters.

GA'LLY-WORM. *See* JULIDANS.

GA'LVANISM. (From Galvani, professor of anatomy at Bologna, the discoverer of some of the phenomena connected with this form of electricity in the year 1790.) Under this term are frequently included the phenomena of *Voltaic electricity* (which see). We shall here limit it to the apparent evolution of electricity by the contact of different metals: this is best observed by the muscular contractions which are produced in the leg of a frog recently killed, when two different metals, such as zinc and silver, tin and gold, &c., one of which touches the crural nerve, and the other the muscles, are brought into contact. Every time the metals touch each other the limb becomes powerfully convulsed; and if the experiment be made with a dead rabbit, so that one of the metals be in contact with the brain, and the other with the muscles of the extremities, the whole body of the animal is strangely agitated. Similar experiments have been made upon the bodies of criminals shortly after execution. These results, which have till lately been considered to depend upon the effects of electricity excited by the contact of the metals upon the nervous and muscular systems, led Volta to his celebrated researches, which terminated in the discovery of the *Voltaic battery*. Nearly all the cases, however, of the apparent production of electricity by contact have been satisfactorily traced by Faraday to chemical action. *See* VOLTAIC BATTERY.

GA'LVANO'METER. An instrument for ascertaining the presence of a current of electricity, especially Galvanic or Voltaic electricity, by the deviation which it occasions in the magnetic needle. The simplest form of galvanometer is a magnetic needle poised upon a point, and surrounded by one or more coils of copper wire covered with silk, the ends *a* and *b* being either left free, or terminating in two small copper cups containing mercury, for the convenience of communication with the source of electricity. When this needle is placed parallel to the coil, and in the magnetic meridian (as represented in the margin), it immediately deviates when the electric current passes through the coil; and the deviation is either to the east or the west, according to the direction of the current. *See* ELECTRO-MAGNETISM.



GA'MBA. A technical term in Mammalogy, applied by Illiger to the elongated metacarpus or metatarsus of the Ruminants and Solipeds.

GAMBO'GE. A yellow gum resin much used as a pigment, and in medicine as a drastic and nauseating purge. It is chiefly imported from Ceylon in cakes rolled up in flag leaves, and is the produce of the *Garcinia cambogia* and of the *Stalagmites cambogioides*.

GAME LAWS. The principal statutes relating to game, now in force, are the 7 & 8 Geo. 4. c. 29., the 9 Geo. 4. c. 69., and 1 & 2 W. 4. c. 32., by which last statute important changes have been made. By the common law, which followed the old forest law, as introduced into this country by the Normans, all game was the property of the king; no person whatsoever could enjoy the diversion of sporting, unless authorized by royal grant of a chase or free warren; and to kill a deer was deemed almost as heinous an act as to kill a man. But although at common law no persons could with impunity encroach upon the kingly prerogative of pursuing game, yet those were exposed to the additional pains and penalties of the statute law who committed this offence not being possessed of a certain rank or dignity, or of a certain amount of landed property. Strictly speaking, then, the superior condition in life of a party constituted the ground of his exemption from additional punishment, and not, as commonly supposed, a qualification to do that which was altogether interdicted, whether to the peer or the peasant. But the aggravated offence under the statutes, namely, that of sporting without rank or fortune, being in later times severely visited, while the original offence at common law was passed over, rank and fortune were, in the end, looked upon as a qualification; and a freehold estate of 100*l.* a year, or leasehold for 99 years of 150*l.* a year, or being the son and heir apparent of an esquire or person of superior degree, were accounted as so many qualifications. The statute law prohibited any persons whatsoever, whether qualified to kill game or not, from making it the subject of sale or merchandise.

By section 2. of the new act above mentioned, the word "game" shall include hares, pheasants, partridges, grouse, heath or moor game, black game, and bustards. The principal alterations in the law made by this act are, 1st, that all qualifications are now done away with, and that any person taking out a proper certificate may kill game on his own land, or that of another person with his leave; and 2dly, that every person having such a certificate may sell game to any person licensed to deal in it according to the act, who again is at liberty to retail it without restriction.

Most trespasses and offences relating to game are punishable upon summary conviction, before magistrates. The most serious of these offences is what is called night poaching. After two convictions before a magistrate for this offence it becomes a misdemeanor, to be proceeded against by indictment, and punishable by transportation for seven years, or imprisonment and hard labour. Night poaching committed by three or more persons in company together is a misdemeanor in the first instance, and punishable by transportation for fourteen years, or imprisonment and hard labour.

GAMES, have been resorted to in all ages, and among all nations, for the purposes of mental or physical exercise or amusement, according to their nature and peculiarities. The games of the ancient Greeks were, in their original institution, religious solemnities, founded, according to tradition, by gods and heroes, and continuing to be celebrated in their honour. They were the most important national assemblies, which brought the citizens of all the independent states of Greece in contact; and these festal communions (πανηγυρεις) served as the most popular bonds of social union among all who bore the Hellenic name. The four principal were, the Olympian, Pythian, Nemean, and Isthmian. (See those several articles. See *Wachsmuth's Historical Ant. of the Greeks*, chap. 1. part ii. s. 22.; *Hermann's Antiquities*, Oxf. trans., sec. 10. See also the treatise of Barbeyrac on the *Morality of Games*.)

GA'MING. In Law. All common gaming houses are nuisances in the consideration of English law. The first statute against public gaming is the 33 H. 8. c. 9. By 9 Ann. c. 54. securities given for the repayment of money lent for purposes of gaming are void; and any person losing and paying 10*l.* at one sitting may, within three months, recover the same, with costs, in any court of record. By 5 & 6 W. 4. c. 41. if any person make, draw, or execute any note, bill, or mortgage for a gaming debt, and actually pay to any indorsee, holder, or assignee of such note, bill, or mortgage, the sum thereby secured or any part thereof, such money shall be deemed to be paid on account of the person to whom such note, bill, or mortgage was originally given (upon the illegal consideration), and shall be deemed to be a debt due from such last-mentioned person to the person who shall so have paid such money, and shall be recoverable by action at law in any court of record. But though the English law has always been hostile to the practice of gaming, it has never been found sufficiently strong, or perhaps sufficiently willing, to suppress it. In London and in other large towns the existence of "Hells," as the places of resort for gaming are appropriately called, is notorious to all the world. In many of the Continental states gaming houses are licensed, and large revenues are in many instances derived from this source. It is only within the last two years that the French government abolished the practice of granting licences

Previously to that period the privilege of keeping gaming houses was farmed by a company, for which they paid the government 6,000,000 francs annually.

GA'MMARINES, *Gammarina*. (Gr. καμμαρον, *a lobster*.) The name of a family of Amphipodous Crustaceans, having the genus *Gammarus*, or the sand-hopper, as the type.

GA'MMONING. The rope by which the bowsprit is

bound firmly down to the cutwater, in which is a hole for the purpose of reefing several turns of it.

GA'MUT, or GAMMA UT. In Music, a scale whereon the musical notes are disposed in their several orders. Its invention is attributed to Guido Aretino, a monk of Tuscany; it is also called the harmonical hand, from Guido having made use of the figure of the hand to demonstrate the progression of his sounds.

GA'NGLION. (Gr. γαγγλιον, *a knot.*) An enlargement in the course of a nerve. A tumour in the sheath of a tendon.

GA'NGLIONEURA. (Gr. γαγγλιον, and νευρον, *a nerve.*) A name applied by Rudolphi to the Molluscous and Articulate divisions of the animal kingdom, which are characterized by a ganglionic type of the nervous system. In the articulated gangliated animals the ganglia are always disposed symmetrically along the middle line of the body, and brought into communication by a double chord: these have therefore been termed *Homogangliata.* In the Mollusca, on the contrary, the ganglions are dispersed, and placed at a distance from each other, and from the mesial plane, and are frequently unsymmetrical in their arrangement: these have therefore been termed *Heterogangliata.*

GA'NGRE'NE. (Gr. γρασειν, *to feed upon.*) The loss of vitality of a part of the body.

GA'NGWAY. The sea term for a narrow passage way; particularly that part of the upper deck which is next the ship's side, between the fore and main masts.

GA'NNET. *See* PELECANUS and SULA.

GAOL. (Fr. geole, Lat. caveola, *a cage.*) A prison. The present law as to building, repairing, and maintaining gaols and houses of correction, is regulated by the statutes 4 G. 4. c. 64., 5 G. 4. c. 12. and c. 85., and 2 & 3 Vict. c. 56. (1839), the latest act on the subject. No gaol can be erected under any less authority than that of an act of parliament. There must now be at least one common gaol and one house of correction in every county. Gaolers are appointed by the high sheriff; by 4 G. 4. they are allowed to exercise no other trade or office, and must reside within the prison. As to the discipline and management of gaols, see PRISON.

GAPE. In Ornithology, the opening between the mandibles of birds.

GA'RDANT, or GUARDANT. In Heraldry, a term applied to a beast when represented full-faced, as looking at the spectator. *Re-guardant,* when looking backwards.

GA'RDEN. (Fr. jardin.) A piece of ground, generally of limited extent, and attached to a house, and enclosed, in which are cultivated various vegetables, fruits, and flowers, for the use of man. In the infancy of civilized society, all these objects were cultivated in one enclosure; but as mankind advanced in civilization and refinement, and the number of objects to be cultivated increased, it became necessary to adopt separate departments; and culinary vegetables came to be cultivated in the kitchen garden, fruits in the orchard, flowers in the flower garden, ornamental trees and shrubs in the shrubbery or pleasure grounds, and timber trees in plantations, woods, and forests. Hence the word garden, in the extensive sense in which it is at present used, is no longer confined to a limited enclosure, but extends to an extensive area, in which are contained various scenes of utility, comfort, convenience, and luxury.

GA'RDENING. The art of cultivating a garden, which, as we have seen in the preceding article, comprehends a great variety of objects and scenes. All these at the present time are generally included under the following heads: — Horticulture, which comprehends the culture of culinary vegetables and fruits; floriculture, which includes the culture of ornamental and curious flowers, shrubs, and trees; arboriculture, which implies the culture of trees or shrubs used for various purposes in the arts and in general economy; and landscape gardening, or the general disposition of the scenery or landscape about a country residence. Horticulture includes the culture of the kitchen garden and orchard; floriculture, the culture of flower gardens, botanic gardens, shrubberies, and pleasure grounds; arboriculture, the culture of nurseries for fruit and forest trees and shrubs; and landscape gardening, the formation and management of lawns, roads, walks, lakes, ponds, and artificial rivers, of rock work, and of every description of objects in artificial scenery which come under the denomination of ornamental or picturesque. *See* HORTICULTURE, BOTANIC GARDEN, ARBORICULTURE, and LANDSCAPE-GARDENING.

GA'RGARISM. (Gr. γαργαριζειν, *to gargle.*) A wash for the throat.

GA'RNET. A mineral of which there are several varieties. The *precious garnet* is transparent, red, and in crystals or rounded grains; it is a silicate of alumina and iron, and is used for ornamental jewellery. *Common garnet* is often found in large crystals and masses, translucent, and of various colours.

GA'RNISHMENT. In Law, a warning or notice given to a party to appear in court or give information; a technical term, used only in one or two instances. Thus *garnishment* or warning is given to a third person, in whose hands money is attached within the liberties of the city of London by process out of the Sheriff's Court, who is termed a *garnishee.*

GA'RRISON. (Modern Lat. garnitio, *military stores, &c.*) A body of forces disposed in a fortress to defend it against the enemy, or to keep the inhabitants of the town where it is situated in subjection. The term *garrison* is sometimes used synonymously with *winter quarters,* viz. a place where a number of troops are laid up in the winter season without keeping the regular guard.

GARRO'TE, THE. A mode of capital punishment employed in Spain. The criminal is seated on a stool with his back to a stake. A tight collar is passed round his throat, of which the ends nearly meet; the executioner, standing behind him, twists them closer by means of a screw: the death is instantaneous.

GA'RTER, ORDER OF THE. The various accounts respecting the original foundation of this noble order are for the most part well known. The commonly received story, which attributes it to the dropping of the Countess of Salisbury's garter, is contradicted by many recent writers, who attribute its institution to Richard I., who tied thongs of leather as marks of distinction round the legs of several of his officers at the siege of Acre. In the opinion of Dr. Meyrick (*On Armour*, vol. ii. p. 54.), the garter is nothing more than a symbol of unity. The order was, however, either founded or restored by Edward III., and, according to general opinion, either in the year 1344 or 1350. The first of these dates was that of a festival in which the king formed himself and his associates into a company, under the patronage of St. George; but nothing is said respecting the garter until the latter year. The statutes of the Garter have been revived and augmented by King Henry V., Henry VIII., and George III. in 1805. It was generally called the order of St. George until the reign of Edward VI.; St. George of Cappadocia, the tutelar saint of England, being likewise patron of this order. It originally consisted of twenty-six knights, the king being the chief; and the same number is still retained, with the addition of princes of the blood royal as supernumeraries. In the beginning of the present century, it was estimated that eight emperors and twenty-eight foreign kings had been members of it. The number has been since much augmented. It is the most ancient of all the lay orders of chivalry, and may rightly be accounted the noblest in the world. The college of the order is held at the chapel of St. George, in the castle of Windsor. The vestments and ensigns of the order are, the mantle of blue velvet, changed to purple by Queen Elizabeth, but restored to the original colour by Charles I.; the surcoat, now of crimson velvet; the hood, which is now fixed to the mantle, a cap of black velvet with an aigrette of heron's feathers being worn on the head instead of it; the collar of gold, composed of twenty-six pieces made to resemble garters, with the badge of the order (the figure of St. George and the Dragon) pendent from it; and the garter, of blue velvet. The lesser George, as it is called, is attached to a blue ribbon, passing from the left shoulder to the right hip. The officers of the order are, the prelate (the bishop of Winchester for the time being); the chancellor (the bishop of Salisbury); the register (the dean of Windsor); garter king at arms (this officer combines two functions, being herald to the order of the garter, and also principal king at arms, the highest officer of the Herald's College under the earl marshal); and the usher or black rod. It has also a dean and twelve canons, &c., with twenty-six pensioners, or poor knights. The most authentic work on the order of the Garter is that of the learned antiquary Elias Ashmole, printed at London in 1715.

GAS. (Probably from the German *geist,* or spirit.) This term is applied to all permanently elastic fluids, or airs differing from atmospheric air.

GAS ILLUMINATION. Under the head CARBURETTED HYDROGEN, we have adverted to two gaseous compounds of carbon and hydrogen, which perform an important part in the economy of gas illumination. There are several other analogous compounds, which are produced in various relative proportions during the destructive distillation of pit coal, and which, therefore, are more or less concerned in the history of *coal-gas,* which, as far as gas illumination is concerned, may be defined as a mixture of two or more hydro-carburetted gases or vapours with small portions of other gaseous bodies, among which free hydrogen and carbonic oxide are the most common.

The application of the gases produced during the destructive distillation of pit coal to the purposes of illumination is a very modern invention. But the germ of it may be traced back exactly 100 years; for the first mention of the production of a permanently elastic and inflammable gas from coal occurs in the *Philosophical Transactions* for 1739, in which there is a paper by the Rev. Dr. Clayton describing a method of

filling bladders with what he calls the *spirit of coal*, obtained by distilling coal in a retort in the open fire. He says, "I filled a good many bladders therewith, and might have filled an inconceivable number more; for the spirit continued to rise for several hours, and filled the bladders almost as fast as a man could have blown them with his mouth, and yet the quantity of coals distilled was inconsiderable. I kept this spirit in the bladders a considerable time, and endeavoured several ways to condense it, but in vain; and when I had a mind to divert strangers or friends, I have frequently taken one of these bladders and pricked a hole therein with a pin, and compressing gently the bladder near the flame of a candle till it once took fire, it would then continue flaming till all the spirit was compressed out of the bladder; which was the more surprising, because no one could discern any difference in the appearance between these bladders and those which are filled with common air." Dr. Clayton seems also to have observed those curious phenomena which have lately excited so much attention under the terms *exosmose* and *endosmose;* for he goes on to say that he found "that this spirit must be kept in good thick bladders, as in those of an ox or the like; for if I filled calves' bladders therewith, it would lose its inflammability in twenty-four hours, though the bladders became not relaxed at all."

Dr. Hales (in his *Vegetable Statics*) and Dr. Watson (in his *Chemical Essays*) have each alluded to the properties of the gas from coal; but it was not until the end of the last century that the practicability of substituting coal gas for other inflammables, as a means of lighting streets and buildings, became an object of attention.

The idea of applying coal gas to economical purposes seems first to have occurred in 1792 to Mr. William Murdoch, then residing at Redruth, in Cornwall. His apparatus consisted of an iron retort, with tinned copper and iron tubes, through which the gas was conducted to a considerable distance; and there, as well as at intermediate points, was burned through apertures of varied forms and dimensions: he also washed the gas with water, and used other means for its purification. In 1798 Mr. Murdoch constructed a larger and improved apparatus for the purpose of lighting Boulton and Watt's celebrated manufactory at Soho, near Birmingham, which, on the occasion of the peace in 1802, was publicly illuminated by the same means. (See *An Account of the Application of Gas from Coal to Economical Purposes*, by Mr. W. Murdoch, *Phil. Trans.* 1808, p. 124.)

But the attention of the public in London was first called to this important subject by the experiments of Mr. Winsor, who, in 1803 and 1804, lighted the Lyceum theatre, and shortly afterwards one side of Pall Mall, with gas from coal. From that period, the manufacture of gas suggested itself as a lucrative speculation; several private gas works were erected, and companies were formed for the purpose of carrying it on upon an extended scale. Oil lamps were soon after banished from all the great thoroughfares of the metropolis; and in the course of from ten to fifteen years not only was every street and alley illuminated from the same source, but it was generally introduced into shops and houses; was adopted in the theatres and other public buildings; was carried into the suburbs; and has now become general in every town and city of the empire.

When coal is subjected to what chemists term *destructive distillation*, that is, when it is heated red-hot in close vessels, it yields a great variety of complicated products, which, as far as our present subject is concerned, may be classed under three heads: namely, first, permanent gases; secondly, vapours, which are condensable into the liquid or solid state by cooling; and, thirdly, the fixed or residuary matter, which remains in the retort. The object of gas manufacture is to separate these from each other, and so to purify the gaseous products as to render them fit for combustion.

The apparatus employed for this purpose consists, first, of the *retorts*, as they are called, or cast-iron cylinders, in which the coal is subjected to heat; secondly, the apparatus for condensing the solid and liquid products; thirdly, the purifiers, by which the gas is cleansed from various matters which would be prejudicial if retained; and, fourthly, the gasometers, in which the purified gas is ultimately received, and which are connected with the service pipes for its distribution. The following is a brief description of these several parts: —

The retorts are usually about 7 feet 6 inches long and 1 foot in diameter, and in the shape of an arched cylinder; from five to eight of them are set in brickwork, so as to be heated red-hot by one fire. Each retort has what is called a mouth-piece, which projects from the front of the brickwork, and from which there rises an upright pipe, about 12 feet high and 3 or 4 inches in diameter, and which carries the products of distillation into the hydraulic main. Each retort has a cover, which is kept in its place by holdfast screws, and rendered air-tight by lime luting. The hydraulic main is a long horizontal pipe, 12 or 14 inches in diameter, and into which the dip pipe of each retort dips, so as to be sealed by the fluid which fills the lower half of the main, and which is allowed to run off at that level. This fluid is of a very complicated nature; but tar and ammoniacal liquor are the terms applied to its chief component parts; and these, being condensed in the hydraulic main, serve to seal the ends of the dip pipes, and are constantly running off into what is termed the tar vessel. Those products of the distillation of the coal which are not thus in the first instance condensed are conveyed, by a pipe continued from the hydraulic main, through a series of tubes or other contrivances, so as to expose a large and cold surface. This part of the apparatus is called the *condenser;* in it the more volatile vapours are brought to the liquid state, and are collected in an appropriate receiver. The uncondensed gases then pass on to the *purifiers*, which are vessels so constructed as to expose them to the action of a very large surface of lime and water, or of slaked lime, by which carbonic acid and sulphuretted hydrogen are abstracted; and thence the gas, now purified, passes into the *gasometers*, where it is stored up for use.

It would be impossible within the limits of this article, and indeed irrelevant to the object of this Dictionary, to enter into minute details respecting the structure, uses, and arrangement of each of the above parts of the apparatus for the production of coal gas; but the reader may be enabled to form some idea of the importance and extent of the whole manufacture from the following outline of results.

There are, in the largest gas manufactories of London, from 500 to 600 retorts, each of which is charged four times a day with 2 bushels of coal. They are ranged in rows on either side of the retort house, and the flues from their respective furnaces are generally so arranged as to meet in one central chimney; but as coke is the usual fuel used for heating the retorts, there is commonly little or no smoke. Each chaldron of coals submitted to distillation yields on an average 24 gallons of tar, ammoniacal liquor, and other condensable products, and 12,000 cubic feet of purified gas; while there remains in the retorts a chaldron and a quarter of coke. To purify those 12,000 cubic feet of gas there is required about one bushel of lime, which, after its removal from the purifying vessels, is used for making mortar, luting the retorts, and other similar purposes; while the fetid liquor which runs from it is transferred to the ashpits of the furnaces, where it is consumed by evaporation, its vapour passing through the fire, and tending materially to preserve the bars of the furnaces by keeping them cool.

In a well-conducted gas establishment two men are required for the management of sixteen retorts, which are charged four times in the 24 hours; the retorts are kept in constant work throughout the 24 hours, so that relays of men are required for the night-work. In small gas works the agitators of the purifiers are worked by hand; but in the larger establishments there are usually one or more steam engines on the premises for this purpose, and for pumping water, lifting coals, and other heavy work.

The number and dimensions of the gasometers will of course vary with the circumstances, space, and extent of the manufacture: in the works of the Chartered Gas Company, at their station at Westminster, there are twenty-one gasometers, each containing on the average 30,000 cubic feet.

There are, besides those parts of the apparatus above adverted to, and which are essential to the manufacture, several other ingenious and beautiful contrivances in our larger gas works, which may be considered as auxiliaries. One of these is the station meter; a large instrument through which the whole of the gas passes in its way to the gasometers, and by which its volume is registered, so that the quantity made during any given time can be immediately ascertained, and the weekly, monthly, or annual production accurately determined. The gas meter was invented by Mr. Clegg, formerly engineer to the Chartered Gas Company. It consists of a hollow cylinder, which is made to revolve upon its axis by the ingress and egress of gas into and from the three compartments into which it is divided, the cylinder being partly immersed in water; and by a train of wheel work connected with it the number of its revolutions in a given time is registered, and the number of cubic feet of gas which traverse it in a minute, hour, day, or year, shown upon separate dials. The invention of this instrument forms an important epoch in the history of gas manufacture; for it is now constructed upon any scale, and is applicable to any case of the consumption of gas; so that by having a meter in each house of a size appropriate to the number of burners employed, the companies are enabled to sell their gas by measure, and have an unerring check upon the quantity which each instrument consumes.

Another beautiful contrivance, adopted in most of our gas works, is that by which the pressure upon the gas in the main and service pipes is adjusted; so that when a

number of burners are suddenly extinguished, or suddenly lighted, in any part of the district which is supplied, there shall be an intimation of the change at the works, so as to prevent either excess or deficiency of supply; or, in other words, to prevent the lights which remain from flaring up on the one hand, or being nearly or quite extinguished on the other. This is effected by a small and nicely adjusted gasometer connected with the service main, and which, by its rising and falling with diminished or increased pressure of the gas within the main, points out the necessity of opening or shutting the valve by which the gas is admitted from the gasometers to a greater or less extent. This small regulating gasometer has a vertical rod connected with it, which carries a pencil made to bear upon a paper cylinder properly ruled and divided, and which is made to rotate upon its axis by communication with a timepiece; so that every change of pressure which takes place during the night, for instance, is shown by the aberration of the line. Mr. Crossley, to whom the improvement of the gas-meter, by which it is rendered universally applicable, is due, is also the inventor of these pressure registers.

The following particulars may serve to give an idea of the quantity of gas annually consumed in London, of the quantity of coal required for its production, and of the general economy of this mode of illumination. It must also be borne in mind that gas is an article of increasing consumption; and that in proportion as attention is paid to its manufacture, and more especially to the *fittings* as they are called — that is, to the pipes, cocks, burners, and other arrangements required for its use and distribution in houses — it will become more generally adopted in private dwellings, so as, in all probability, to supersede ere long all other sources of artificial light. Nor are the attempts which have been made to employ it as a source of *heat* unimportant. Gas stoves, although hitherto made upon very erroneous principles, are not without their advantages; and it has been promisingly applied to some of the operations of cooking.

The oldest of the London gas works is the establishment belonging to the Original Chartered Company. They have three stations: the largest situated in Peter Street, Westminster; the second in Brick Lane, St. Luke's; and the third in the Curtain Road, Shoreditch. This company consumes 50,000 chaldron of coals annually, the produce of which, in gas, may be estimated at about six hundred million cubic feet, or about eighteen million seven hundred and fifty thousand pounds *weight* of gas. It may be assumed that each chaldron of coals weighs 2880 lbs., and yields an average produce of 12,000 cubic feet of purified gas. The prime cost of gas is about four or five shillings per 1000 cubic feet; the usual retail price is from seven to ten shillings per 1000 cubic feet.

The Chartered Company probably supply about a fifth part of the whole of the gas consumed in London and the suburbs; so that the total annual consumption of coal employed for this important manufacture in the London district only probably exceeds two hundred and fifty thousand chaldrons, and the quantity of gas produced for the supply of this district amounts annually to three thousand million cubic feet. The *weight* of this quantity of gas exceeds 75 millions of pounds; and the *light* produced by its combustion may be considered as equivalent to that which would be obtained by the combustion of 160 millions of pounds of mould candles of six to the pound.

The operations of the London Gas Light Company, which was established in the year 1833, are also on a scale of great magnitude. This company was called into existence by the dissatisfaction which existed among gas consumers at the defective supply, both in quantity and quality, previously afforded. Their works, situated at Vauxhall, are not only the most powerful, but the most complete in arrangement of any in the world. From this point their mains ramify to a prodigious extent in Middlesex as well as Surry; and by the admirable mode in which they are laid, aided by the power of their works, they are enabled to supply gas at Highgate Hill (seven miles off), with the same precision and in the same abundance as at Vauxhall. The extent of their pipes exceeds one hundred and fifty miles.

The cost of light equivalent to that of seven mould candles (six to the pound) is, in coal gas, $\frac{3}{4}$*d.* per hour; in an Argand oil lamp, 3*d.* per hour; in mould candles, $3\frac{1}{2}$*d.* per hour; in wax candles, 1*s.* 2*d.* per hour.

GA'SKET. A platted cord, by which the sails, when furled, are kept bound up close to the yards or gaffs. The same term is applied to the platted hemp used for packing the piston of the steam engine and its pumps.

GA'STEROPODS, *Gasteropoda.* (Gr. γαστηρ, *the belly*, and πους, *a foot.*) The name of a class of Molluscous animals, comprehending those which have a ventral muscular disc of greater or less extent, adapted for creeping. The class is divided, according to the modifications of the breathing organs, into the orders *Pulmonata, Nudibranchia, Inferobranchia, Tectibranchia, Pectinibranchia, Tubulibranchia, Scutibranchia,* and *Cyclobranchia.* The carinaria, in which the ventral foot is reduced to a rudimental compressed plate, forms the type of an aberrant group or order, called *Heteropoda.* The pulmonated snail or slug may be regarded as types of the Gasteropodous Mollusks.

GASTRÆ'UM. (Gr. γαστηρ.) A term in Zoology, applied to the whole of the prone or under surface of an animal's body.

GA'STRIC JUICE. The peculiar fluid secreted by the stomach, and essential to the process of *digestion.* When collected from the stomach of an animal killed while fasting, it is transparent and saline, but during digestion it is distinctly acid; and Dr. Prout found that the free acid which it contains is the *muriatic.* One of the most characteristic properties of the gastric juice is its solvent power over the varieties of animal fibre, or albumen, and the facility with which it coagulates milk, and then dissolves the coagulum. *See* DIGESTION.

GASTRI'LOQUUS. *See* VENTRILOQUIST.

GASTRI'TIS. Inflammation of the stomach. It is attended by great irritability of the stomach, indicated by hiccup, vomiting, and much pain and general uneasiness: the pulse is small and hard, and there is fever, attended by prostration of strength. It is a very dangerous disease, and requires prompt treatment; especially bleeding, general and local; blisters; hot bath, or fomentation. The constant sickness generally prevents the exhibition of any of the ordinary remedies. When it arises from poison, the stomach pump and other distinct treatment is often requisite.

GASTROCHÆ'NA. (Gr. γαστηρ, and χαινω, *I gape.*) A genus of Bivalve Mollusks, in which a large hiatus or gape intervenes between the closed valves on the ventral aspect of the animal. The mantle is perforated, opposite to this gape, by a small aperture for the passage of the foot; and is prolonged posteriorly into two muscular tubes or siphons. The Gastrochenes inhabit burrows, which they perforate in the substance of madrepores or calcareous rocks, and they line their perforations with a calcareous tube.

GA'STROCNE'MIUS. (Gr. γαστηρ, and κνημη, *the leg.*) The muscle which forms the protuberant part of the leg: the calf.

GA'STRODYNIA. (Gr. γαστηρ, and οδυνη, *pain.*) A painful affection of the stomach, often attendant upon dyspepsia.

GA'STROMANCY. (Gr. γαστηρ, and μαντεια, *prophecy.*) A kind of divination practised among the ancients by means of words issuing or seeming to issue from the belly. This term is applied also to a species of divination performed by means of glasses or other round transparent vessels, in the centre of which certain figures appear by magic art.

GAUGE, or GAGE. *See* GAGE.

GAUGE-POINT, is a term used in Gauging to denote the diameter of a cylinder whose altitude is one inch, and its content equal to that of a unit of a given measure. For example, the old wine gallon contained 231 cubic inches. The diameter of a cylinder of the same capacity, and whose altitude is one inch, is 17·15 inches; which, therefore, is the gauge-point for this measure.

GA'UGING, in Mensuration, is the measuring of the capacities of vessels, chiefly casks, barrels, vats, &c., and determining the contents of the substances contained in them. The principles of gauging are those which geometry furnishes for the measurement of solids in general; but as the contents of vessels of the kind now mentioned are so frequently required to be known, at least approximately, for the purposes of commerce and the collection of the revenue, a set of technical rules and appropriate instruments have been contrived, by the help of which the art can be, and generally is, practised mechanically by those who are utterly ignorant of the principles on which it depends. The instrument generally used for the purpose is the *gauging-rod*, or *diagonal-rod*, by which the contents of a cask are inferred from its diagonal length, measured from the bung to the extremity of the opposite stave at the head. On one face of a square rule, generally about four feet long, is a scale of inches for taking the measure of the diagonal; and on the opposite face is a scale expressing the corresponding contents of the cask in gallons. It is obvious that this method of proceeding can only give approximate results, on the supposition that all casks are similar solids. (See *Symon's Practical Gauger; Leadbetter's Treatise on Gauging; Hutton's Mensuration*, &c.)

GAUGING RULE. *See* SLIDING RULE.

GAULT. A provincial name in the east of England for a series of beds of clay and marl, the geological position of which is between the lower and upper greensand.

GAU'NTLET, RUNNING THE. A barbarous punishment of former times, by which the criminal was obliged to pass between the seamen arranged in two rows, and provided with knotted cords, with which they flogged him.

GAUZE. A textile fabric generally made of silk, and said to have been invented in Gaza, a city of Palestine.

GA'VELKIND. An old English custom or tenure annexed to all lands in the county of Kent not especially exempted, by which the land of the father is equally divided at his death among all his sons, or the land of the brother among all his brethren if he have no issue of his own. Tenure in gavelkind is considered by Blackstone to have been in the nature of free socage. In most places the gavelkind tenant had the power of devising by will before the Statute of Wills. The same custom seems to have been prevalent in Wales, where all gavelkind lands were made descendible to the heir at common law by stat. 34 & 35 H. 8. c. 36. In Kent the lands have been for the most part disgavelled, or deprived of their customary descendible quality, by particular statutes; but lands in Kent are presumed to be gavelkind, unless the contrary be shown.

GA'VIAL. *See* CROCODILE.

GA'VOT. (Fr. gavotte.) In Music, an air for a dance, which has two strains; the first having usually four or eight bars, and the second eight or twelve more, each of which are played twice over. It is of a brisk nature.

GAZE'LLE. The name of a small, swift, and elegantly formed species of antelope, the *Antelope dorcas* of Linnæus; long famed for the peculiar lustre and soft expression of its large dark eyes.

GAZE'TTE. A periodical paper, published at short intervals, containing articles of general intelligence. Both on the Continent and in England such sheets were generally termed *Mercuries* in the first times of their invention, and appeared only occasionally; the earliest among ourselves were published during the general apprehension from the presence of the Spanish armada; but some doubt has been lately thrown on the authenticity of the specimens preserved in the British Museum. The first gazette produced in France (under that title) was in 1631: the first in England in 1665, when the court resided at Oxford on account of the plague of London. From that period the Gazette has regularly appeared twice a week, containing such notifications as are either published by the court or the government, or such as are authoritatively required by law in private transactions. The name Gazette is said to be derived from Gazzeta, a small Venetian coin, being the price that was paid for one of the flying sheets of commercial and military information (notizie scritte), which were first published by that republic in 1563. *See* NEWSPAPER.

GAZETTEE'R, is applied in England to a work containing a brief account of all or any of the countries of the world, arranged in alphabetical order. To this class belong *Brookes's General Gazetteer*, and similar works.

GA'ZONS, in Fortification, are the turfs, or pieces of earth covered with grass, with which the faces of works raised of earth are lined in order to keep them up and preserve their form.

GECKO'TII. A family of lizards, having for its type the genus *Gecko*; in which most of the species present a curious organization of the foot, by which the sole is converted into a sucker, enabling the animal to creep up vertical walls and along ceilings against gravity, like the flies upon which they feed.

GEHE'NNA. A term in Scripture, adopted from the usage of the Jews to signify hell or the place of eternal punishment. The word is a slight corruption of Gehinnou, or the Valley of Hinnom, in the neighbourhood of Jerusalem, wherein, at a place named Tophet, it was recorded that certain idolatrous Jews had sacrificed to Moloch. The sewers of the city were emptied into this hollow, and perpetual fires were kept up to consume the noxious matter, and prevent pestilential effluvia. Hence, it is said, the name of the place came to be used metaphorically in the sense above described. From this word seems to be derived the old French gehenne, *torture*; and from thence the common word gêne, *constraint*.

GE'HLENITE. A mineral in small grey or yellow crystals, found in the valley of Fassa in the Tyrol, named in honour of Gehlen the chemist. It is a ferrosilicate of alumina and lime.

GE'LATIN. (Lat. gelu, *ice*.) An abundant proximate principle in animals. It is confined to the solid parts of the body, such as tendons, ligaments, cartilages, and bones, and exists nearly pure in the skin; but it is not contained in any healthy animal fluid. Its leading character is the formation of a tremulous jelly, when its solution in boiling water cools; and it may be repeatedly liquified, and again gelatinized, by the alternate application of heat and cold. Isinglass, glue, and size are various forms of gelatine, the first being this substance in a very pure state. Its most distinctive chemical character is the formation of a dense white precipitate when its solution in warm water is poured into an infusion of galls or other form of vegetable tannin. A solution of one part of gelatin in 5000 of water is rendered slightly turbid by the addition of a strong tincture of galls. Gelatin is a nutritious article of food. The ultimate components of gelatin are 47·8 carbon, 7·9 hydrogen, 16·9 nitrogen, 27·4 oxygen.

GE'LATINES. Mr. Kirby thus renders the term *Radiaires molasses* of Lamarck, by which are designated the same radiated animals as those called *Acalephes* by Cuvier: the bodies of these Radiaries are generally of a gelatinous consistency.

GELD (Ger. *money*), in the Laws of the Saxon and other Teutonic communities, is used in the sense of any fine, rent, or payment: for instance, the fine paid as compensation for an injury, as in the compound *weregild*; the compensation for murder, *dannegild*, &c.

GEM. (Lat. gemma.) In Sculpture, a precious stone, used for the purpose of sculpture. The practice of carving gems is of remote antiquity, though it is doubtful whether they were able to cut the diamond or use the emerald and topaz for sculptural purposes. The stones usually selected are rock crystal of different colours, jasper, chalcedony, onyx, cornelian, and blood stone. Among the Greeks the art was carried to great perfection; but having fallen with the other arts into disuse, its revival was effected in Italy in the 15th century, and modern masters have more than rivalled some of the ancient productions.

GE'MINI. (Lat. *the Twins*.) The third constellation of the zodiac, into which the sun enters about the 21st of May in each year. The Twins are named from Castor and Pollux; sometimes, also, from Apollo and Hercules. The constellation is easily distinguished by means of two conspicuous stars of the second magnitude near together; Castor being that which is furthest to the west, and Pollux that which is furthest to the east.

GEMMI'PARES, *Gemmipara*. (Lat. gemma, *a bud*, and pario, *I produce*.) The animals which propagate by buds, as the *hydra*, or fresh-water polype, &c.

GEMS, ARTIFICIAL. These are made of a very fusible, transparent, and dense glass, or *paste*, as it is called, containing a large proportion of oxide of lead, and generally some borax: the colours are given by metallic oxides. Much of their perfection depends upon the skill with which the exact tint of the real stone is imitated, and upon the care with which they are cut and polished.

GE'NA. (Lat. gena, *the cheek*.) A term applied in Zoology to the region between the eye and the mouth, generally extended over the zygomatic arch.

GENDA'RMES, or GENS D'ARMES. In the 15th and 16th centuries, the heavy French cavalry, which constituted the only national force, were termed Gendarmes, or men-at-arms. Each lancer had four, five, or six followers on horseback, attached to him in various capacities; so that a *lance*, in the language of historians of that epoch, comprehends six or seven men. After the cuirass and lance had become obsolete, the name of gendarmes ceased to be thus applied. It was afterwards transferred to a corps of police. In consequence of the unpopularity of this corps in Paris, the gens d'armes were abolished after the revolution of 1830, and a new police force organized under the title of Municipal Guard. (See the *Ency. des Gens du Monde*.) In all the German states, there is a body of mounted military police, with this appellation, of which the Germ. equivalent, is "Landdragoner."

GE'NDER. (Lat. genus.) In Grammar, the designation of sex by the form of a word. (See an elaborate article in the *Penny Cyclopædia*.)

GENEA'LOGY. (Gr. γενεα, *family*, and λόγος, *description*.) The pedigree of each family. A series of several persons, descended from a common progenitor, is called a line. A direct line is either ascending (father, grandfather, &c.: in the civil law particular names were given to seven degrees in this line), or descending (son, grandson, &c.). The collateral lines comprehend the several lines which unite in a common progenitor; and are either equal or unequal, according as the number of degrees in the lines is the same or different. The collateral relations on the father's side are termed in the civil law cognati, on the mother's agnati.

GE'NERAL, in the Army, is, next to field marshal, the highest military title adopted by the European states. Like most military designations, it owes its origin to the French, who, about the middle of the 15th century, conferred the title of lieutenant-general on the individual to whom the monarch (by virtue of his birth the commander or general of the national forces) entrusted the superintendence of the army. The title of general is conferred either on the commander-in-chief of the forces of a nation, or on the commander of an army or grand division; it is also given to the officers next in rank to the general, who, besides performing functions peculiar to their own offices, frequently act as the substitutes of their superior, with the designation of lieutenant-general and major-general.

GE'NERAL ASSE'MBLY OF THE CHURCH OF SCOTLAND. *See* ASSEMBLY, PRESBYTERIANS.

GENERALI'SSIMO. A title conferred, especially by the French, on the commander-in-chief of an army consisting of two or more grand divisions, each under the superintendence of a general. According to Balzac, this dignity was first assumed by Cardinal Richelieu on the occasion of his leading the French army into Italy; but

the term does not appear to have found favour among the other European states.

GENERA'LITY. A French territorial division under the government prior to the Revolution. The generalities amounted in all to 34. This division was principally with reference to the collection of taxes.

GENERALIZA'TION, in Logic, has been defined as the act of comprehending under a common name several objects agreeing in some point which we abstract from each of them, and which that common term serves to indicate. (*Whateley's Logic*, p. 388.)

GENERA'TION, or GE'NESIS, in Geometry, denotes the formation or production of a geometrical figure or quantity. A line is said to be *generated* by the motion of a point, a surface by the motion of a line, and a solid by that of a surface. A sphere or spheroid is generated by the revolution of a semicircle, or semi-ellipse, about its diameter; and a circle by the revolution of its radius about one of its extremities. The figure thus produced, or generated, is called the *generant;* and it is a general property of every such figure that its area or content is equal to the product which arises from multiplying the generating quantity into the length of the path described by its centre of gravity. All quantities may be considered as generated by motion; and hence arose the terms *fluxion* and *fluent* in the infinitesimal analysis.

GE'NESIS, BOOK OF. *See* PENTATEUCH.

GENE'THLIAC. (Gr. γενεθλιάζειν; from γένεθλον, *a birth.*) An ode or other short poem composed in honour of the birth of an individual.

GENE'VA. *See* GIN.

GE'NIA. (Gr. γενειον, *the chin.*) Terms in Anatomy compounded of this word, and applied to muscles attached to the chin.

GENI'CULATE. (Lat. genu, *the knee.*) Bending abruptly in an obtuse angle, like the knee when a little bent.

GE'NII, called by the Eastern nations Genn or Gien, are a race of beings created from fire, occupying an intermediate place between man and angels, and endowed with a corporeal form, which they are capable of metamorphosing at pleasure. They are said to have inhabited this earth many ages before the creation of man, and to have been at last driven thence for rebellious conduct against Allah. Their present place of abode is *Ginnistan*, the Persian Elysium; but they are represented as still interesting themselves deeply in the affairs of this earth, over which they exercise considerable influence. Every one is aware of the important part which the genii perform in the interesting stories of the East; and indeed a more correct idea may be formed of their origin, characteristics, and history, from a perusal of the *Arabian Nights' Entertainments*, than can be conveyed by the most elaborate dissertation. For an account of the superstitions of the modern Arabs in regard to genii, see *Lane's Modern Egyptians.*

GE'NITIVE CASE. (Lat. genitivus, *generative.*) That inflexion of the noun which denotes the relation of property. *See* GRAMMAR.

GE'NIUS. (Lat. gigno, *I produce.*) According to the belief of the old Italian races, especially the Etruscans, the genius was a spiritual agency of very indeterminate character, which seems to have been appropriated not only to every human family and individual as a companion, but to every god, and even to places and things. This conception was altogether foreign to Grecian mythology, although in later times it became mingled in that of Rome with the Grecian notions respecting demons. (*See* DÆMON.) As, for instance, in the idea of a double genius, good and bad. Censorinus (*De Die Natali*) says, " The genius is that god under whose protection every mortal is born and lives." Hence the worship of the genius was closely connected with all domestic ceremonies and feelings: the marriage bed was *lectus genialis;* the day of the genius, *genialis dies*, sacred to mirth and relaxation; the genius accompanied human fortunes in their vicissitudes (Vultu mutabilis, albus et ater — *Hor.*); and death was typified by the figure of a genius with a lamp reversed. The genii of places were usually represented and worshipped under the figure of snakes. Whether there is any connection between the Italic genius and the djinn of oriental nations (*see* GENII) is a doubtful point.

GENS. In Ancient History, a clan or sect, forming a subdivision of the Roman people next in order to the curia or tribe. The members and houses (*familiæ*) composing one of these clans were not necessarily united by ties of blood, but were originally brought together by a political distribution of the citizens, and bound by religious rites, and a common name, derived probably from some ancient hero. This common name, which distinguished the *gentiles* or members of the same clan, was the second of the three borne by a Roman citizen, and was specially termed the *nomen*. It is supposed that each of the *curies* originally contained ten *gentes*, and that each of these was represented in the senate by one of its members. (See *Vico, Scienza Nuova; Niebuhr's History of Rome*, 2d ed. p. 387.)

GE'NTIAN. In Pharmacy, the root of the *Gentiana lutea*, a plant abundant in the Swiss and Austrian Alps, and in the mountainous parts of Germany. An infusion or tincture of gentian root is an excellent stomachic bitter.

GE'NTIANA'CEÆ. (Gentiana, one of the genera.) A natural order of herbaceous Exogens, inhabiting most parts of the world. They are very near to *Apocynaceæ*, from which they differ in their herbaceous habit, permanent corolla, want of milk, and in many other characters. From *Scrophulariaceæ* they are distinguished by their regular flowers, the stamens of which are equal in number to the lobes of the corolla; but they are with difficulty distinguished if the flowers are absent. Lastly, they have a natural relation to *Cinchonaceæ*, inasmuch as the genera *Mitreola* and *Houstonia* have both been mistaken by good botanists for Cinchonaceous plants. Their chief characteristic sensible property is an intense bitterness, which resides both in the stems and roots, rendering them tonic, stomachic, and febrifugal; on which account the roots of *Gentiana lutea* and others are admitted into all pharmacopœias. Many of the species are beautiful in the hands of the cultivator. The prevailing colours are red and blue.

GE'NTILE. (Lat. gens, *nation.*) The original meaning of the Latin word *gentilis* is, one of the *same* kith or nation with the speaker. In a later age of Latinity, individuals of foreign or barbarous races were called Gentiles. (*Auson;* and *Cod. Theodos.*) The Jews designated all not professing their religion indiscriminately as " the nations," τα ἔθνη (N.T.); and hence the Greek word ἐθνικος (whence our heathen and the corresponding Latin word gentile) became used to signify Pagans, in opposition to Christians and Jews. The word *gentilis* is used in this sense by St. Jerome, Prudentius, and Christian writers of that age in general. The jealousy with which the Jews regarded all foreign nations, and the bigotted obstinacy with which they clung to their notions of their own peculiar sanctity and favour in the sight of God, are well known. The earlier half of the history of the Acts contains the account of the struggle which Christianity maintained against these prejudices before it finally subdued them, even in the breasts of the Apostles and first teachers themselves. The design of Christ that all nations should be admitted to the benefits of his mission, is clearly shown in many of his own words and actions; but, upon his crucifixion, his followers appear in the first instance to have shrunk from carrying out this great principle. Their preaching is confined for some time to Jerusalem; and there, it is to be remarked, they are treated with no severity, and obtain considerable success. But upon the appointment of the deacons, who appear to be Hellenists — much more lax in their Judaical notions and prejudices than the Jews of Palestine, — and upon the preaching of Stephen, which was probably the first bold declaration of the equality of the Gentile with the Jew, the anger of the people is immediately roused; the flame of persecution breaks suddenly forth; the disciples are driven from Jerusalem, and scattered abroad in places where they are brought more in contact with foreigners; and the vision which is vouchsafed to Peter recognizes distinctly the claim of the Gentiles to the benefits of the Gospel. The observance of certain Jewish ceremonies continued, however, for a long time to be a stumbling-block to the most devout and sincere Christians. St. Paul combats the notion of the necessity of submitting to some of these, — especially circumcision; yet even he feels obliged to make some indulgence to the prejudices of the Judaizing party. In after times this party occupied one distinct division of the Christian world, split itself into various sects, such as the Ebionites and Nicolaitans, and for a long time exercised considerable influence even within the pale of the church.

GE'NTLEMAN. (The English word *gentle*, in its original sense, signifies one belonging to a *race* or *family;* Lat. gens.) In Heraldry, a rank expressed in Latin by the term generosus. All entitled to coat-armour are gentlemen; but the name is more commonly applied to the lowest rank of those who have no other distinguishing title. Gentlemen by blood were those who could show four generations of gentlemen, both in the paternal and maternal line. Those who could not prove this, but against whom the contrary was not known within memory of man, were gentlemen by prescription. Gentlemen were also created by letters patent of the king. Officers (not menial) of the king's household, persons holding a royal commission, civil or military, persons who had taken a degree in the liberal arts, and persons adopted by gentlemen, were considered entitled to this rank, which has now been long obsolete as a distinction.

GENTLEMEN PENSIONERS. In England, a band of forty gentlemen, entitled esquires, whose office is to attend the king's person to and from the Chapel-Royal, and on other occasions of solemnity. They were instituted by Henry VIII.

GE'NTLES. The maggots or apodal larvæ of the flesh fly (*Musca carnaria*), and other Diptera, are sometimes so called.

GE′NUS. (Lat.) In Zoology, that distinct but subordinate group of animals which gives its name as a prefix to that of all the species of which it is composed.

GENUS. In Logic, one of the predicables, which is considered as the material part of the *species* of which it is affirmed. *See* LOGIC, PREDICABLE.

GENUS. In Music, the general name for any scale of music. If a scale proceed by tones, it is called the *diatonic* genus; if between the tones semitones are introduced, it is called the *chromatic* genus. When the subdivisions are smaller, as quarter tones, it is called the *enharmonic* genus.

GE′OCE′NTRIC. (Gr. γη, *earth*, and κεντρον, *centre.*) A term frequently used in Astronomy, signifying literally *having the earth for its centre.* The apparent motion of any planet, as seen from the earth, is called its *geocentric motion.* The *geocentric latitude* of a planet is the angle formed by a straight line, supposed to be drawn from the planet to the earth, with the plane of the earth's orbit or the plane of the ecliptic. *Geocentric longitude* of a planet is the angle at the earth formed by two straight lines, one of which is drawn to the first point of Aries, and the other to that point of the ecliptic which is intersected by a perpendicular circle, the plane of which passes through the earth and planet. *Geocentric* is opposed to *heliocentric*, which refers to the centre of the sun. These terms are only used in speaking of bodies belonging to the solar system. The fixed stars are at such prodigious distances, that they are referred to the same points in space, whether we consider them as seen from the earth or the sun.

GE′ODES. (Gr. γεωδης, *earthy.*) Nodules of ironstone, hollow in the centre. Rounded pebbles having an internal cavity lined with crystals are also so called.

GEO′DESY (Gr. γη, and δαιω, *I divide*), literally signifies the *division of the earth*, in which sense it is synonymous with land surveying; but it is usually employed in a more general sense to denote that part of practical geometry which has for its object the determination of the magnitude and figure either of the whole earth, or of any given portion of its surface. In this sense it comprehends all the geometrical or trigonometrical operations that are necessary for constructing a map of a country, measuring the lengths of degrees, &c. In order to construct an accurate map, or determine the form and dimensions of a country, it is necessary, in the first place, to determine the absolute distances between the several stations or points; secondly, to determine the azimuths of the lines thus measured, that is, their situation with respect to the meridian; and thirdly, the differences of latitude and longitude of the stations. The operations necessary for determining the absolute distances, comprehending the measurement of a base, the observation of angles, the computation of the sides of the triangles, and their reduction to the same level, are called the *geodesical* or *geodetical* operations; while those which are required for determining azimuths and latitudes are called the *astronomical* operations. The determination of the figure and dimensions of the earth is a problem of very great importance to astronomy and geography, and has accordingly at all times been a subject of much interest to mathematicians; but it is only since towards the middle of the last century that operations on an adequate scale for its solution have been undertaken in different parts of the world. For the results of the more important of these operations, see DEGREE.

GEO′GNOSY. *See* GEOLOGY.

GEO′GRAPHY. (Gr. γη, and γραφω, *I describe.*) The description of the earth. The etymology of the term indicates the nature and extent of this department of knowledge, which, in fact, embraces every thing relating to the circumstances and condition, natural or artificial, of the globe which we inhabit. The immense variety of subjects comprehended in the science of Geography are usually arranged under three great divisions, — *Mathematical, Physical*, and *Political Geography.*

Mathematical Geography. — This division of geography has for its object the determination of the form and dimensions of the earth, its relations with the celestial bodies, the relative positions and distances of places on its surface, and the representation of the whole or portions of its surface on globes or maps.

In order to describe the earth the first element that must be ascertained is its general form. That the surface of the earth is convex, is apparent even to the senses. Let a spectator stand on the sea shore, and attend to the successive appearances of a ship proceeding to sea. First, the lower part becomes invisible; then the whole hull; and, lastly, the masts and rigging, the lower parts disappearing first. Now this phenomenon can only be explained by the convexity of the portion of the water between the ship and the spectator; and when the curvature of the sea is recognized, the conclusion can scarcely be avoided that the land, abstracting from its local inequalities, participates in the same curvature, and that the earth is a round body. The same conclusion is drawn from the gradual coming on of day and night, and the deplacement of the stars in proceeding towards the north or south; for if the earth were flat, the sun, in appearing above the horizon, would illumine the whole of its surface at the same instant; and on the supposition of its being either flat or cylindrical, the pole star would maintain the same elevation, whereas to the traveller who advances northward it gradually appears more elevated, and to him who advances southward more depressed. All these appearances are observed in the same manner on whatever part of the earth we are placed; and from them alone the globular form of the earth might be inferred, even if the fact had not been placed beyond doubt by the voyages of circumnavigators. Astronomers in modern times have indeed discovered that it is not a perfect sphere, being flattened in a slight degree at two opposite points (which are the poles of rotation); but the deviation from perfect sphericity is so small, that for all the purposes with which geography is concerned it may be neglected without sensible error. *See* FIGURE OF THE EARTH.

In order to determine the relative positions of points on a sphere in the most commodious manner, mathematicians refer them to two *great circles*; that is to say, circles formed by the intersection of the surface of the sphere by a plane passing through its centre. The earth is a body which revolves about an axis of rotation; the position of this axis, therefore, with respect to the celestial constellations, determines one great circle, namely, the *equator*, or the circle which is equally distant from the two poles of rotation, and divides the globe into two opposite hemispheres. The equator, therefore, being marked out by nature, or by the apparent revolutions of the celestial bodies arising from the real diurnal rotation of the earth, is a circle to which all places are most conveniently referred: and it has this property, that it never undergoes any change of place on the sphere; for astronomers have proved that since the date of the earliest observations, the poles of rotation, and consequently the equator, have always maintained the same invariable position on the earth's surface.

The distance of a place from the equator cannot be directly measured; but by means of astronomical observations we can determine that distance in aliquot parts of the earth's circumference, that is, in degrees of a great circle. It is not, however, sufficient to know how many degrees a place is distant from the equator. It is necessary, also, in order to distinguish it from all other places, to know how it is situated with respect to a certain *meridian*, or great circle perpendicular to the equator, and consequently passing through the poles. In reference to the diurnal rotation of the earth, all meridians are in precisely the same circumstances; the choice is consequently entirely arbitrary, and geographers, as well as astronomers, generally select that which passes through the capital of their own country as the circle to which they refer all other places. The equator and the assumed meridian thus form the co-ordinates of the sphere. The distance of any place from the equator, measured on the arc of the meridian, is the *latitude* of the place; and its distance from the assumed meridian, measured on a circle parallel to the equator, is its *longitude*; and when the latitude and longitude of any place are both known, the position of the place itself is entirely determined. The latitude of a place is ascertained by observing the height of the pole above its horizon; and the longitude of one place in respect of another, by the interval of time which elapses between the passage of any celestial body over their respective meridians. *See* LATITUDE and LONGITUDE.

Besides the rotatory motion about its axis, the earth has also a motion of revolution about the sun, which is completed in the course of one year. The first of these motions causes the succession of day and night; the second the vicissitudes of the seasons, and the inequality of the length of the natural days. These two last phenomena depend on two circumstances: — 1st, that the axis of the earth is not perpendicular to the plane of the ecliptic, or the plane in which the annual revolution is performed; and 2d, that the extremities of this axis, or the two poles of rotation, continue to be directed to the same points of the celestial sphere during the whole time of the revolution. Hence it follows that the plane of the equator, though invariable in respect of absolute space, is continually changing its position in respect of the sun; and the apparent effect is the same as if the sun had a vibratory motion in the heavens, rising above the plane of the equator E E one half of the year, and falling below it during the other half. When the sun is in the equator at S, the two poles of the earth n and s are in the great circle which divides the illuminated from the dark hemisphere. When the sun reaches his greatest northern declination at S′, the il-

luminated hemisphere is *a* E *a'*, and the north pole *n* comes considerably within it. On the other hand, when the sun's declination is south, as at S'', the south pole *s* comes into the illuminated hemisphere, while *n* is left in darkness. When the sun is at S his apparent diurnal motion is performed in the equator, and the days and nights are of equal length all over the world. The angle which the planes of the equator and ecliptic make with each other is about $23\frac{1}{2}^{\circ}$; consequently, since the greatest declination of the sun from the equator is the same quantity, it must happen that at midsummer the sun is $23\frac{1}{2}^{\circ}$ to the north of the equator, and at midwinter $23\frac{1}{2}^{\circ}$ to the south of it. The inequality of the natural days is an immediate consequence of the sun's declination; for as the solar rays come to the earth parallel, one half of the globe must always be illuminated at once, and the other half in darkness; consequently when the sun declines $23\frac{1}{2}^{\circ}$ to the north of the equator, all that part of the earth which is within $23\frac{1}{2}^{\circ}$ of the north pole will remain, while the earth performs its diurnal revolution, within the illuminated hemisphere. A small circle of the sphere parallel to the equator, and at the distance of $23\frac{1}{2}^{\circ}$ from the pole, is called the *polar circle;* and at this latitude the sun, when at his greatest declination, comes exactly to the horizon at midnight, without setting; consequently the length of the longest day is twenty-four hours. At the equator the length of the day is always twelve hours; and from the equator to the polar circle the length of the longest day is greater and greater as the latitude increases. At the pole the sun is one half of the year above the horizon, and the other half below it; and from the polar circle to the pole the length of time the sun continues above the horizon without setting increases with the latitude from twenty-four hours to six months. The two small circles of the sphere parallel to the equator, which limit the sun's greatest declination, are called the *tropics;* and the whole surface of the globe is divided by the two tropics, and the two polar circles, into five *zones* or spaces; namely, the *torrid zone*, which is included between the two tropics, or extends $23\frac{1}{2}^{\circ}$ on either side of the equator; the two *temperate zones*, or the spaces included between the tropic and polar circle in each hemisphere; and the two *frigid zones*, or the spaces between the poles and their respective polar circles. These may be called the astronomical divisions of the globe, as they depend on the position of the earth's axis of rotation with respect to the plane of its orbit, and are determined by astronomical observations.

Physical Geography has for its object the description of the principal features of the earth's surface, as consisting of land and water; the extent and configuration of the continents and islands; the elevation and direction of the mountain chains; the conformation of the plains and valleys; their altitude above the level of the sea; and the soil, climate, and animal and vegetable productions of different countries. It embraces also the various phenomena of the ocean, which may be classed under the term *Hydrology;* the depth of the sea, and the inequalities of its depth, its saltness and temperature; the direction and velocity of currents, the tides, the polar ice, &c. In like manner it comprehends also many of the questions which are usually treated under the terms *Meteorology* and *Climate;* the mean temperature of different countries; the height of the snow line; the prevailing winds; the barometric pressure; the quantity of annual rain, of evaporation, &c.; and the effect of all these circumstances on the condition of the human race.

On casting our eye on a globe or map, we immediately perceive the very unequal distribution of land and water on the surface of the earth. The land occupies a very little more than one third of the whole surface, and the water all the remaining portion. Nor is the inequality of the distribution in respect of the two hemispheres less remarkable. Of the whole land about four fifths is situated in the northern hemisphere, and the remaining one fifth in the southern. In a general view, the land consists of three great masses: the *old continent*, which comprehends Europe, Asia, and Africa; the *new continent*, or America; and *New Holland*,—which are separated from each other by the great oceans. The general features of the two continents differ remarkably. In the old continent the general direction of the land, and of the great mountain chains, is from west to east, almost parallel to the equator; while in America the general direction is from north to south, along the meridian. Thus the four great systems of mountain ranges in Asia,—namely, the Altai, the Thian-chan, the Kuen-lun, and the Himalaya,—all stretch from west to east; and the Andes, which extends from one extremity of America to the other, ranges in the perpendicular direction from north to south. Another striking feature of the land is, that all the great peninsulas are pointed to the south pole. This is the case with South America, Africa, Arabia, Hindostan, Malaya, Cambodia, the Corea, Kamtschatka, California, Alaska, Greenland, Florida, Italy, &c.; in short, the only two exceptions are Yucatan in the Gulf of Mexico, and Jutland in the German Sea, which are both formed of alluvial land, and may therefore be supposed to owe their formation to partial influences which have not operated on the great continental masses. This similarity of disposition can only be attributed to the agency of some mechanical cause; and the phenomena strongly suggest the idea of the terraqueous masses having been shaped into their existing forms by the action of a great wave or current flowing from the southern to the northern pole. (See ATMOSPHERE, CLIMATE, GEOLOGY, TIDES, WIND, &c. See also an excellent article on this subject by Dr. Traill in the *Encyclopedia Britannica.*)

Political Geography considers the earth as the abode of mankind; and has for its object the description of all that relates to the moral or social condition of the different nations; their language, religion, government, degrees of civilization; and the population, resources, and local relations of different countries. This part of geography is consequently related to history and statistics, and does not fall within the scope of this work. (See *M'Culloch's Geographical Dictionary; Murray's Encyclopedia of Geography;* the large work of Malte Brun, of which there is an English translation; the *Dictionnaire Géographique Universel;* the *Systems of Malte Brun and Balbi abridged*, published by Black; and, for recent discoveries, the *Journal of the Royal Geographical Society of London.*)

GEOLOGY. (Gr. γη, *the earth;* λογος, *a discourse.*) Till within the last five-and-twenty years geology consisted of a very limited collection of facts, strung upon amusing but insufficient theories and hypotheses; but it may now be said to have taken its place amongst the rigid and exact sciences. It requires for its successful exposition not only an intimate acquaintance with the mineralogical history of the crust of the globe, but it also involves a series of extensive and distinct inquiries respecting the physical and chemical causes that are and have been active in producing present and past changes; and it branches out into several distinct investigations connected with the discovery of organic remains, in the successful pursuit of which no small share of zoological and botanical information are requisite, and which also demand the aid of comparative anatomy.

There is this therefore to recommend geology, that it excites a distinct interest in the external characters of a country or district, independent of the beauties or ruggedness or sublimity of its aspect, or of its geographical peculiarities, and endeavours to trace a connection between its *exterior* features and *interior* structure; and in these its simplest details it bears upon agriculture, and ultimately upon all those numerous arts in which mineral substances are concerned. The farmer should be a geologist, and so should the architect: the miner and the mineralogist *must* be so. But this is, as it were, the mere title of the volume; for when we come more narrowly to peruse its contents, we do indeed find it "as a book wherein men may read strange matters." It is full of relics, so extraordinary as to arrest the attention of the most superficial inquirer, and to awaken the deepest interest in the philosophic observer: it is thronged with records of strange and mighty changes and convulsions; of revolutions in climate, and in the genera and species of the organic creation; it carries the mind back to a period indefinitely remote, when our present continents were at the bottom of an ocean, from which they seem to have been elevated sometimes by the slowest degrees, and at others by a more rapid and violent cause, and when both sea and land were tenanted by distinct tribes and races of extraordinary animals and vegetables; it shows that every thing as we *now* find it has been gradually and successively developed as it were, and that man himself has appeared but late upon this singular stage.

In this article our principal object will be to give an outline of the present state of geology, and an explanation of the terms of the science. To attain this object, the works which we have principally consulted, and from which, with the kind permission of their authors, we have made copious extracts, are those of Lyell and De la Beche: the explanatory diagrams are chiefly from the same sources. To them, and to the works of Phillips, Bakewell, Mantell, and Buckland, and to the *Transactions of the Geological Society*, we must refer our readers for details which would have been inconsistent with the objects of this Dictionary.

In tracing out the present appearance of the earth's surface, and in examining minutely the effects of causes now in action, there is nothing, as Hutton has said, in which *we* can distinctly perceive either the evidence of a beginning or the prospect of an end. Geometers have taught us that in the midst of all the fluctuations which can possibly take place in the elements of the orbits of the planets by reason of their mutual attraction, the general balance of the parts of the system will always be preserved, and every departure from a mean state periodically compensated. But, in saying that *we* can discover nothing that points to a beginning or threatens an end, we only mean that mere human powers are as yet inadequate to such a discovery.

There are, it is true, some circumstances in the physical constitution of our own planet which do *obscurely* point to an origin and a formation, but from them nothing distinct can be concluded. On the other hand, neither the researches of astronomy nor of geology give us the slightest grounds for regarding either our system, or the globe we inhabit, as of *eternal* duration ; in short, if we would speculate to any purpose, either upon the former state of our globe, or upon the succession of events which from time to time may have changed the condition and the form of its surface, we must confine our views within limits far more restricted, and to subjects much more within the reach of our capacity, than either the beginning or the end of the world. These, indeed, were almost the sole inquiries of the older geological school, the favourite speculations of a race of geologists now nearly extinct. Within the limits of the present century even geology has undergone an entire change of character, and is, as we have already remarked, brought within the list of the inductive sciences. Geologists now no longer ransack their imaginations for theories of the formation of the globe from chaos, or bewilder themselves with its hypothetical transformations ; but they aim at a careful and accurate examination of the records of its former state, and of the indisputable evidences of former life and habitation which the organic remains of its strata afford.

These wonderful wrecks of a former state of nature, preserved, like ancient medals and marbles in the ruins of an extinct empire, afford a kind of rude chronology, by the aid of which the successive depositions of the strata in which they are found may be marked out in epochs more or less definitely terminated, and each recognized by some peculiarity which enables the diligent observer to recognize the deposits of any period, in whatever part of the globe they may occur. And, so far at least as investigation has hitherto gone, these deposits are in the same *order of succession* in every part of the world.

But, in using these terms, we must not forget how very little we do actually know of the earth's surface. We talk of certain strata extending over the *whole* globe, forgetting that nearly three fourths of it are covered by the waters of the ocean, and that consequently of that portion we can know but little,and that little imperfectly; and that of the fourth which remains in the shape of dry land not one thousandth part has been at all examined, or at least not investigated. Again, we speak of the *crust* of our globe, and of the *bowels* of the earth, and the *depth* of the sea, and the *loftiness* of mountains, forgetting how insignificant all these things really are, compared with the entire bulk of our planet ; that our deepest mines hardly penetrate to a depth surpassing the ten thousandth part of the distance from the surface to the centre ; that the profoundest recesses are mere scratches upon the surface ; that the loftiest hills and most inaccessible mountains are only as grains of dust and of sand sprinkled on the surface of one of our moderate-sized artificial globes.

Such being the real state of our information, and such the limitations to which all further pursuit is subjected, we may well be animated by the magnitude and extent of the inquiries which this limited range displays. " And finding, even in these restricted bounds, the amplest proofs of order and design, the mind is naturally led to the sublimest inferences respecting what is unseen, and even to the conception of a power and intelligence to which we may well apply the term *infinite;* since we not only see no limit to the instances in which they are manifested,but find, on the contrary, that they continually open upon us in increasing abundance, in proportion as we are enabled to extend our sphere of observation and inquiry ; and that as the study of one prepares us to understand and appreciate another, wonder follows on wonder, till our faculties become bewildered in admiration, and our intellect falls back on itself in utter hopelessness of arriving at an end."

We may now state of what the external film or cuticle of the globe appears to consist, and examine how far we are justified in surmising respecting the nature of its deeper-seated parts, and of such portions as are out of the reach of actual inspection.

We say that the crust of the earth is *stratified*, because it consists chiefly of distinct strata or layers of different materials. These differ in depth and extent ; but, what is most essential to our present purpose, they follow each other, on the large scale and as masses, in an apparently regular and uniform succession in all places, districts, and countries where they admit of examination and have been attentively studied. They appear, in most instances, to rest upon, and are blended with, invaded, and in some few instances overflowed as it were by, substances which are *not* distinctly stratified, and which most geologists have agreed in calling *unstratified rocks*. The former, or the stratified rocks, from their texture and contents have apparently been formed under water ; and some of them, especially the uppermost series, abound in fossil remains of the organized kingdom. The *unstratified* rocks, on the other hand, are in many instances of indisputable volcanic origin ; and others, from their position, texture, and effects upon their neighbours, are also presumed to be of igneous formation. *Water*, therefore, on the one hand, and *fire* on the other, seem to have been the great agents to which the present aspects of the earth's surface are referable. In proceeding to enumerate the principal *divisions* of the stratified rocks in their order from above downwards, we must remind the reader that the series is frequently rendered irregular by the deficiency of one or more of its members ; and that sometimes whole series of strata seem to have been removed from certain districts by causes which we shall afterwards endeavour to trace, constituting what have been called *denudations*.

In this diagram A represents the crystallized or *unstratified* rocks, presumed to be of igneous origin, upon which lie the *stratified* rocks, B, C, and D. The rocks A were formerly called *primitive*, and were supposed to be the original crystalline crust of the globe, upon which the strata B C D had been subsequently deposited ; but it is now supposed that the rocks B, C, and D have been upheaved by the subsequent intrusion of A by volcanic agencies from beneath.

The substances which usually constitute the ground we tread upon are produced chiefly by causes in daily operation—soils and detritus of various kinds washed down from the neighbouring hills by the influence of rain and torrents, and forming what have been generally called *alluvial* deposits : these are more or less associated with matters probably of a similar but a more ancient origin, and which, suspected by some to be relics of the deluge, have been termed *diluvial* deposits ; such as *gravel* and *boulder stones*.

We then find in many parts of England and elsewhere occasional patches of what have been termed *tertiary* rocks, which often are of singular interest, and frequently consist of detached and insulated deposits surrounded by other rocks, and, in reference to their neighbours, occupying a position very like that of the water of lakes, inland seas, and gulfs, in relation to a continent ; and, like such waters, being often very deep, but of limited extent : hence they are often designated as *basins*. They consist of clays and calcareous and arenaceous matters, in which are embedded remains of marine animals, blended with fresh-water species, quadrupeds, and even birds. These lie upon chalk, which is the newest rock of the secondary series. They constitute the *supracretaceous* rocks of which the basins of Paris, London, and the Isle of Wight, and parts of Suffolk, furnish instances. Chalk constitutes the uppermost of the secondary series of the European area ; and it is immediately succeeded by certain varieties of sand and sandstone, included by Mr. De la Beche in his *Cretaceous* group. We then (in the same area) come to the *Oolitic* group, composed of calcareous freestone and of lias, resting upon the varieties of red sandstone, and succeeded by coal, mountain limestone, and *old* red sandstone ; and these are followed by the *Greywacke* group, forming the *transition* series of Werner, a part of which has been ably described under the name of *Silurian system* by Mr. Murchison, resting upon a lower portion termed *Cambrian system* by Professor Sedgwick. The Greywacke may be conveniently divided into three portions : — 1. *Upper*, equivalent to the old red sandstone of England ; 2. *Intermediate*, equal to the Silurian system ; and 3. *Inferior*, equivalent to the Cambrian series. These are often made up of fragments of the older series, or contain a few ancient organic relics. They rest upon the *inferior* order of stratified nonfossiliferous rocks, and upon the *unstratified* or primary series.

In endeavouring to trace out the history of the respective strata to which we have adverted, it would, perhaps, be most philosophical to commence our inquiries with the causes that are now active in producing alterations upon the surface of the globe ; to consider the action of changes of temperature, and of water and other agents, that tend to degrade and disintegrate the surface, to wear down its asperities, and to modify the present order of things,—among which earthquakes and volcanos form a prominent feature. But the narrative will be more clear if we first sketch out the history of the *formations*, considering them in reference to their position, their composition, their organic relics, and the purposes to which they are applied in the arts ; and then, having adverted to their relative durabilities and aspects as mountain masses, we may consider the action of rivers, and of the ocean, both as destructive and as renovating agents, tracing out their connection with meteoric phenomena, and with the effects of volcanic fires. We shall thus be

enabled to compare present with past changes, and to form an opinion upon the great controversial question which now seems chiefly to engage theoretical geologists; namely, whether things have always gone on pretty much as we now see them, or whether our globe has been subject to great and destructive changes and convulsions out of the ordinary course of nature.

§ I.

First, then, as respects those superficial and insulated formations constituting the *tertiary* or *supracretaceous* group of rocks. Our knowledge of their distinct existence is chiefly due to the labours of Cuvier and Brongniart, whose *Memoir on the Environs of Paris* was published in 1811. In this part of Europe they form patches or basins; but there is much reason to believe that they have once been more continuous and extensive, and that their present insulated character is, partly at least, due to the elevation of the strata below them, by which they have been broken up, and in part also removed by denudation.

Amongst these formations we may also class many extensive series of rocks in different parts of Europe, which, although they bear records of having been deposited at different and probably remote periods, are still, compared with the strata beneath them, of comparatively modern origin, and belong to the general epoch of the supracretaceous series.

It will easily be understood that one characteristic test of the date or age of a rock formation is to be found in the fossils which are entombed in it. If these are of *genera and species now existing*, it is an inference in favour of modern formation; if the *genera* are extant, but the *species* extinct, we are carried back to a more remote date; and if the *genera* are also extinct, we presume upon a yet more remote period of deposition. It is obvious, also, that other conclusions of great importance may be deduced from the same source, and that the remains of certain quadrupeds, amphibious animals, and fresh-water and marine fish and shells, will announce the existence of dry land, lakes, or seas, at the periods of the respective depositions; — and again, from *alternations* of these deposits, we are often enabled to infer the successive or alternate states of dry land, lakes, and the ocean, upon one and the same spot. All these inferences require to be drawn with the utmost circumspection, and many concomitant circumstances to be taken into the account; but the data, when judiciously used, are of the greatest interest and importance, and give the most unexpected and extraordinary yet philosophical clues to the discovery of a former and very remote state of things upon the surface of the globe.

The tertiary rocks, when tried by the test just hinted at, may be subdivided into three or four periods, founded upon the comparison of their respective fossils; all these periods are distinct from and anterior to that which has elapsed since the earth has been tenanted by man, and which may therefore be called the historical, *recent*, or contemporaneous period.

In the most modern of the above periods, the formations are such as contain fossil testaceous remains, of which the *greater part* are referable to recent species. In some of these there is an immense preponderance of recent species, and the formations pass by insensible gradation into those of the historical period; as in part of Sicily and the district about Naples. In others, the recent species vary from one third to one half of the entire number; as in the subappenine hills and in the English crag. The formations of the next period contain a minority only of imbedded fossil shells of recent species (Touraine and the beds of the Loire); and in the last, they are of such very sparing occurrence, as to indicate what may be considered as the first commencement of the existing state of the animal creation (Paris and London basins).

These three periods or formations Mr. Lyell designates by the terms *Pliocene*, *Miocene*, and *Eocene*. (Pliocene, from πλειων, *major*, and καινος, *recent*, because the major part of the fossil testaceæ of this epoch are referable to recent species; Miocene, from μειων, *minor*, a minority only of fossil shells embedded in the formations of this period being of recent species; Eocene, from ηως, *aurora*, because the very small proportion of living species contained in these strata indicates the dawn, as it were, of the present state of the animal creation.) To give some idea of the contents and arrangement of these strata, we may briefly refer to the Paris, Hampshire, and London districts.

A descending section of the strata near Paris presents the following orders of succession: — The uppermost rock consists of various marls and siliceous compounds, containing organic remains, which characterize it as of fresh-water formation; to this succeed marls, sand, and limestone, with marine shells; then fresh-water marls, siliceous limestone, and gypsum, with the bones of animals; then a coarse limestone abounding in marine remains, often hard, and applicable to architectural purposes; and lastly, lying upon the uneven surface of the chalk, plastic clay, with beds of sand containing lignite, amber, and shells both of marine and fresh-water animals.

In this extraordinary assemblage some of the organic relics are of great interest. The gypseous strata contain the bones of extinct mammalia and other animals, which have been almost recalled, as it were, into existence by the scientific skill of Cuvier, who has given sketches of their probable forms and habitudes. There are the remains of about fifty species of quadrupeds, all extinct, and nearly 4-5ths of them belonging to a division of the order *Pachydermata*, now only represented by four living species; namely, three tapirs and the daman of the Cape. There are a few carnivorous animals, among which are a a species of fox and gennet; — there are the dormouse, squirrel, bat, and an opossum (a marsupial animal, now confined to America and Australia). There are about ten species of birds; and, among the reptiles, crocodiles and tortoises.

Though we shall again advert to the probable and apparent causes of this extraordinary assemblage of relics, it may be worth while to refer to some general points connected with the geology of the Paris district, which seem to explain certain states of the earth's surface then existing.

In the first place, as respects their general arrangement, we find that they do not repose horizontally upon each other, but that there are irregularities, announcing hills and valleys upon the original surface of the chalk on which all these deposits rest. So that the plastic clay and its associates were deposited in these hollows, filling them more or less up: upon this the lowest marine stratum (*calcaire grossier*) was formed, also following the uneven surface beneath. Then came the gypseous deposit, containing land and river shells, with fragments of wood, and the assemblage of skeletons: respecting which it deserves particular notice, that they are often entire, the most delicate extremities being preserved, as if the carcasses clothed with their flesh and skin had been floated down soon after death; so that Prevost has suggested that a river may have swept away the bodies of the animals and plants which lived on its borders, or in the akes which it traversed, and may have carried them down to a gulf into which flowed waters impregnated with sulphate of lime, and by which they were gradually consolidated. But whatever was the cause of this singular state of things, it is clear that the deposit of sulphate of lime afterwards ceased; that the relative level of the sea and land apparently became altered; and that marls with sea shells were formed, and pebbles were produced, to which oysters became attached, some of the pebbles being pierced by boring shells. To these deposits succeeds sand with *broken* organic remains, filling up inequalities of surface, and apparently announcing a long-continued action of water. Then those causes which prevented the envelopment of organic remains ceased, and marine exuvlæ became entombed in great abundance; and lastly, to close this eventful history, a varied deposit follows, containing the remains of such animals and vegetables as are known only to exist on dry land, or in marshes or fresh water. This variety of mineral structure has been supposed to result from springs holding various substances in solution entering various parts of a shallow lake. That it was shallow is probable, from the remains of the small seed vessels of fresh-water plants belonging to the genus *Chara*. These curious remains were once supposed to be microscopic shells: they have been called *Gyrogonites* (from γυρος, *curved*, and γονος, *seed*). They occur frequently in fossil formations of different eras.

In the Isle of Wight there is a succession of fresh-water and marine strata, which, as far as fossil contents go, agree in many respects with the Paris district; but in mineral character they are very different. They appear almost exclusively mechanical; and the chemical solutions of silica, and of sulphate and carbonate of lime, which seem to have prevailed about Paris, are not to be traced here. But the bones of mammalia corresponding to the celebrated gypsum deposits of Paris have been disinterred at Binstead, near Ryde.

Here as elsewhere we find signs of an upheaving of the strata, as announced in the different succession of formations, and in the verticality of certain neighbouring beds. In the Isle of Wight, and also on the opposite coast of Hampshire, the fresh-water beds rest upon sand; and there seems, as in the Paris beds, to have been alternations of currents with more quiescent deposits.

A peculiar clay underlies London and the adjoining district, commonly known as *London clay*. It is of various colours, and contains argillaceous and calcareous matters; but the latter rarely so far predominate as to form limestone, or even marl. It contains layers of argillo-calcareous nodules, called *septaria*, and occasional beds of sandstone. Its thickness varies, sometimes exceeding 500 feet. As many of the marine shells found in it have been identified with those of the Paris basin, it is probable that the formations belong to the same epoch. No remains of terrestrial mammals have as yet been found in it, so that we want that evidence of the vicinity of dry

land at the time of its formation; but, that such was the case appears probable from the immense number of seeds and fruits, some of them resembling the cocoa nut and spices of tropical regions. The lower beds of the London clay, called *plastic clay*, are contemporaneous with the equivalent plastic clay of Paris; they contain beds of sand, shingle, clay, and loam, irregularly alternating, and rest upon the irregularities of the chalk beneath.

Although sulphate of lime is not found in the distinct manner noticed in the Paris basin, the clay of London is in many places abundant in it, and it is sometimes found in fine crystals. Its presence is also announced in the hardness of the spring waters that issue from it, as contrasted with the softness of the springs from the plastic clay sands.

In Norfolk and Suffolk there is a rock already mentioned, known under the provincial name of *crag*. It appears from its position and fossil contents to appertain to the newest formations, being yet more modern than London clay, and containing a considerable number of testaceous remains identical with species inhabiting the neighbouring seas. Its mineral character is difficult to define. It generally consists of sand, gravel, and marl; and sometimes presents itself in the form of a soft stratified rock, composed almost entirely of corals and echini, or of loam and clay, containing bones of terrestrial quadrupeds and drift wood, with fragments of older rocks, and gradually passing into alluvium.

Having thus enumerated some of the peculiarities of these tertiary strata, there are two or three questions connected with the formation generally, which, before we leave it, it will be right briefly to advert to. In the first place, the great elevation at which some of these strata occur above the level of the sea would seem to indicate to the superficial observer a retreat or falling of the waters of the ocean. But more accurate inquiry forbids such a conclusion, and leads to another, at first more extraordinary inference; namely, that the land has often been elevated, the proofs and illustrations of which we shall again recur to. Secondly, that the organic remains, animal as well as vegetable, and also the mineral structure of many of these rocks, show that the temperature of these parts of the globe has undergone a considerable declension from its former state; for there are among them evidences of something more than a tropical climate, and of thermal or even boiling springs. The cause of this change of the globe's temperature forms an important subject of discussion with geologists. Some, however, have contended that this evidence of change of temperature, as far as it rests upon organic relics, is insufficient; for, say they, we do not absolutely know that such animals and vegetables, though they *now* require a high temperature, may not at some former period have been adapted to a lower one; and they adduce the Siberian elephant, and a few analogous cases, as proofs. But as we now find every animal and vegetable adapted to their proper situations, we have a right to infer the existence of the same fitness and design at all antecedent periods, and under every possible state of the globe, and therefore to conclude that similarly constituted animals and vegetables have in general had similar habitats.

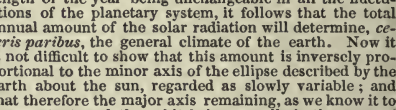
We therefore are obliged to conclude that the earth's surface has suffered a notable decrease of temperature, or at least that there has been a great change of climate over large tracts of the globe. In relation to this question, some have argued the possibility of a decrease of temperature from internal causes,—have considered the whole globe as having cooled from absolute fusion,—and that this process has now only gone to a certain extent, so as that its interior is still glowing. They adduce volcanos and thermal springs as proof of this, and maintain that the warmth which we experience in deep mines is attributable to this central source of heat.

In so far as this hypothesis of a central heat is resorted to to explain a change in *climate*, it seems inadequate; for it is unphilosophical to assume that the same effects would result from such a cause as those which are produced by the influence of the sun's rays and by peculiarities of surface.

Another, and perhaps upon the whole a more plausible explanation of this subject, refers the change to the varying influence of the disposition of land and sea over the surface of the globe. A change of such distribution in the lapse of ages, by the wearing down of old continents and the elevation of new, is a fact which we shall be able to demonstrate; and the influence of such a change on the climates of particular regions, if not of the whole globe, may be fairly concluded from what we know by actual observation of insular, oceanic, and continental climates. Here then, "in language of very high authority," we have a cause on which a philosopher may consent to reason; though whether the changes actually going on are such as to warrant the whole extent of the conclusion, or are even taking place in the right direction, must be considered as undecided till the matter has been more thoroughly examined. It will be observed that this *theory*, for so it may fairly be called, supposes a combination of external and internal causes; the latter raising or depressing the land in proper situations, the former supplying the necessary heat. It also infers the possible return of a warm climate; so that the same situations might be alternately placed under the influence of a raised and depressed temperature, or as it were of an equatorial and polar clime.

Lastly, and the suggestion is sanctioned by the authority of Sir John Herschel, we may look to the astronomical fact of the actual slow diminution of the excentricity of the earth's orbit round the sun. This, as a general cause, affecting the mean temperature of the whole globe, and as one of which the effect is both inevitable and susceptible to a certain degree of exact estimation, certainly deserves to be considered. It is evident that the mean temperature of the whole surface of the globe, in so far as it is maintained by the action of the sun at a higher temperature than it would have were the sun extinguished, must depend on the mean quantity of the sun's rays which it receives; or, which comes to the same thing, on the total quantity received in a given invariable time; and the length of the year being unchangeable in all the fluctuations of the planetary system, it follows that the total annual amount of the solar radiation will determine, *ceteris paribus*, the general climate of the earth. Now it is not difficult to show that this amount is inversely proportional to the minor axis of the ellipse described by the earth about the sun, regarded as slowly variable; and that therefore the major axis remaining, as we know it to be, constant, and the orbit being actually in the state of approach to a circle, and consequently the minor axis being on the increase, the mean annual amount of solar radiation received by the whole earth must be actually on the decrease. We have here, therefore, an evident real cause of sufficient universality, and acting in the right direction, to account for the phenomenon: its adequacy is another consideration. *Herschel's Preliminary Discourse.*) We may suggest the possibility of the three causes adverted to acting in unison, to account for the complicated and curious effects of which we seek an explanation.

Such, then, are the leading considerations arising out of the inspection of the most superficial, and apparently the most recent, of the earth's strata. They suggest a general change in the disposition of sea and land; an alteration in their relative levels, sometimes often repeated; the existence of animals and vegetables now extinct; and a remarkable alteration in the general temperature of the globe. How far the supposed causes of these changes are borne out by observations upon the more ancient formations, will be seen as we proceed in our examination of the descending series.



In the above diagram A A represents the chalk upon which the tertiary strata B C D have been deposited; the latter may be supposed to be of different ages, as indicated by their included fossils, and all of a more recent date than the chalk upon which they lie.

The tertiary rocks rest either upon chalk or upon the geological equivalents of chalk; and the formations of this series constitute a prominent feature of the district which surrounds the London basin, for as soon as we leave the tertiary deposits which characterize the vicinity of the metropolis we enter upon the cretaceous strata. The ranges of chalk in this part of the kingdom are very extensive; and in consequence of their smooth and rounded outline, and the singular cup-shaped concavities and deep hollows in which their sides abound, they confer a monotonous peculiarity on the scenery. They are, however, of much interest in their geological relations. Salisbury Plain and Marlborough Downs form as it were a centre from which the chalk emanates in a north-east direction, through Buckingham, Bedford, and Cambridge shires, and terminates in one direction upon the coast of Norfolk. Another branch, intersected by the valley of the Humber, traverses Lincolnshire, and terminates at Flamborough Head in Yorkshire. The extreme western point of the chalk is not far from Honiton in Devonshire, whence it branches towards the south-east to the Isle of Purbeck, and again appears forming a ridge that crosses the Isle of Wight. Another range of chalk commences near Hungerford in Berkshire, and passes by Alton and Rochester to the coast of Kent, forming the cliffs between Deal and Folkstone. From near Alton another branch passes off, terminating at the lofty promontory of Beechy Head on the coast of Sussex. In these districts some of the chalk hills are of no inconsiderable elevation. Near Dunstable and Shaftesbury, for instance, it forms hills nearly 1000 feet above the level of the sea. Between Lewes in Sussex and Alton in Hampshire there are several similar ele-

vations. Between Alton and Dover the highest point is about 800 feet; and Dover Castle Hill about 470 feet.

The geological history of the chalk offers many matters of interest. Where it is denuded of alluvial and tertiary deposits, and also under these, its surface appears water-worn; and the fissures which it exhibits are often filled with rolled masses, debris and flints. One of its most remarkable characters, in England at least, is the presence of numerous beds of flint in the upper part of the chalk strata; while the lower beds are generally deficient in flints, and argillaceous or sandy. These flints are commonly in distinct nodules, horizontally arranged; but they sometimes are vertical or variously inclined, and occasionally form seams, cutting the chalk at different angles.

The great abundance of organic remains in the chalk has been observed from a very early period; they have recently been carefully examined, and proved to be almost entirely marine. No remains of mammalia have been detected in them; but in Yorkshire and Sussex *reptiles*, one of them of a considerable size, have been observed. The *Mososaurus Hoffmanni*, and a crocodile, fish, and shark's teeth, have been found; as also zoophites, shells, mollusks, and a few crustaceous animals.

The origin of chalk it is difficult to explain. There appears no evidence of its having been deposited from chemical solution; but, on the other hand, it bears marks of a mechanical deposit, as if from water loaded with it in fine division. And upon this principle some gleam of light may perhaps be thrown upon the enigmatical appearance of the flints; for it is found that if finely powdered silica be mixed with other earthy bodies, and the whole diffused through water, the grains of silica have, under certain circumstances, a tendency to aggregate into small nodules; and in some chalk small grains of quartz are discoverable.

Many of our chalk strata afford decided evidence of great disturbances having taken place among them, probably at the period of their elevation from the sea. Illustrative instances of such disturbances are given by Mr. Lyell in the case of the chalk of Newbury in Berkshire, and of the ravine called the Coomb, near Lewes, in Sussex; the latter shows how narrow openings of this kind may have been accompanied by shifts and dislocations, as well as fracture of the strata. The steep declivities on each side and the bottom of the ravine are covered with green turf, and no outward signs of disturbance are visible; but when we examine the section in the neighbouring chalk-pits, we find that there has been much internal derangement.

The evidence of this derangement is shown in the annexed diagram, where A and B represent the chalk with and the chalk without flints on each side of the gap.

These dislocations, or shifts or faults, are common in all strata, though most observed in coal districts, from the importance of the material affected by them.

It must be confessed that such appearances are favourable to the idea of those local convulsions alluded to in referring to certain tertiary strata. For if portions of the secondary rocks emerged from the sea during that period, it is probable that the chalk underwent many oscillations of level; that certain tracts became land and then sea, and then land again; so that parts of the surface first excavated by currents or rivers were occasionally submerged, and after having been covered by tertiary deposits upraised again; and assuming the elevation of the chalk to have been slow, every part of it must have been exposed for some time to the action of the waves: hence the valleys upon its surface, and the broken and rolled flints which overspread it.

In describing the general characters of the chalk, we have limited ourselves to England; but in other countries the mineralogical characters of this formation are such as would lead us to arrange it with other groups, were it not that the included organic remains mark them as of the same epoch: such are the hard limestone and sandstone of the Alps, Pyrenees, and some other primitive countries.

The lower beds of chalk graduate into a variety of sands and sandstones of different aspects and degrees of induration, and often abounding in green particles composed of silicate of iron; whence the term *green-sand*. These beds are associated as one formation, in consequence of the general character of their fossil remains: there is also an argillaceous deposit, provincially known under the name of *gault*, which belongs to the same class.

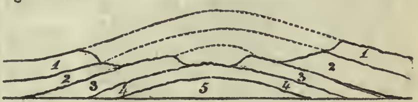
But we now descend by gradual transition to the clays, sands, and limestones of a distinct formation, known in this country as the *Weald rocks*, *Hastings sands*, and *Purbeck beds*. These had generally been confounded with the preceding green-sands of the chalk formation; but a closer examination of their organic remains shows them of distinct origin; for, strange to say, after what we know of the chalk, they abound in terrestrial and fresh-water remains: showing the existence of dry land, and lakes and rivers, before the chalk rocks were formed; and showing also, by the way in which they blend with the sands above, that the change of circumstances which permitted the residence of marine animals over a surface previously inhabited by fresh-water animals was not sudden, but gradual. The examination of these strata has been ably and diligently pursued by Mr. Mantell, whose splendid illustrative collection is now in the British Museum.

The clays and sandstones of this formation contain concretions and veins of argillaceous iron; and these were formerly worked in the Weald of Sussex, as shown by the relics of ancient iron works, and by the abundance of remaining slags, which are at this day still used for mending the roads about Rotherfield, Mayfield, &c. The extensive triangle of which Folkstone, Beechy Head, and Alston are the points, is characterized by this formation, forming greater part of the region intervening between the North and South Downs, known as the *Valley of the Weald*.

This district is very instructive, both as to theoretical and practical geology. It seems highly probable that the chalk has once been continuous, but that it has been washed away by breakers and currents, and fractured by the power which has elevated the strata. In illustration of this important point of theory, the section of the country between the London and Isle of Wight *basins* may be referred to.

If we set out from London, travelling southwards, on leaving the immediate vicinity of the metropolis we ascend an inclined plane of flinty chalk, and then find ourselves on the summit of a declivity consisting chiefly of the different members of the chalk formation. This is called the *escarpment* of the chalk; it overhangs a valley excavated chiefly out of the lower beds of the chalk formation, such as sandstones and gault, and is continuous along the southern termination of the North Downs; so that it may be traced from the sea at Folkstone westward to Guilford and the neighbourhood of Petersfield, and thence to the termination of the South Downs at Beechy Head, where the strata are cut off abruptly by the inroads of the ocean, but where it is evident that they must have at one time been continued.

This denudation is frequently referred to by geological theorists, as rendering it extremely probable that the secondary districts were gradually elevated and denuded when the basins of London and Hampshire were still submarine, and while they were progressively filling up with tertiary sand and clay. It would also appear that subsequently to the emergence of the secondary rocks an immense mass of their upper portions has been removed by the force of water, and that the materials thus carried away were probably conveyed into the depths of the contiguous sea.



The above diagram will serve to explain a valley of denudation, the strata 1, 2, and 3 being to a greater or less extent removed or washed away, and different surfaces of these, and of 4, being now exposed.

We now again advert to the organic contents of the Weald rocks, which, as already stated, are such as indicate the existence of fresh water and dry land before the present chalk deposits were formed; and although some of the inferences of geologists upon this subject appear at first startling and even romantic, they are perfectly fair deductions from the phenomena observed.

The Hastings sands consist of sand and sandstone, with occasional beds of clay and shale, containing silicified wood and fragments of carbonized vegetables, lignite, ironstone, and argillaceous limestone; and the Purbeck beds include varieties of sand and limestone much used for pavement. From the organic remains of these rocks it would appear that they were formed chiefly in fresh water; in lakes, rivers, or estuaries. There is a formation in the Isle of Portland belonging to this series which has been called the *dirt bed*, and which has also been found near Weymouth and elsewhere. It appears from its contents to announce the first appearance of dry land, succeeded by submersion of the same land under fresh water in which the Weald rocks were formed; not suddenly, for there are no marks of violence, but gradually, the shells being tranquilly entombed in the sandy and calcareous deposits.

We shall find, in examining the oolitic rocks upon

which these rest, that they abound in marine remains; so that we must suppose a rise of the land or a depression of the sea to such an extent as to permit the sea-formed rocks to become dry land, upon which tropical plants flourished. Then this land again became in its turn depressed; but so quietly that the trees were apparently left in their natural positions, and even the pebbles and soil not washed away. There is, in short, a great resemblance between these very ancient relics and those of submarine forests of later date upon the coast; except that the former are tropical plants, the latter oak, hazel, &c.

In the sands we find entombed tortoises, crocodiles, plesiosauri and megalosauri, and huge iguanodons. (Mantell, *Phil. Trans.* 1825.)

It is probable that these monstrous reptiles sported in the waters and basked upon the banks of the lake or estuary into which trees and different vegetables were drifted. Now it will be remembered that the sea again resumed its dominion after this state of things, because these strata are covered by the chalk rocks already recognized as marine deposits; and as there are no marks of violence where the Wealden rocks and the green-sands of the cretaceous series come together, but, on the contrary, as they gradually pass into each other, these extraordinary transitions seem to have been gradual, and not attended by any violent or sudden catastrophe.

Such, then, are the remarkable records of the Wealden rocks, and there are analogous cases in other parts of Europe.

The *oolitic rocks* form a very important and curious, but rather complicated series of strata, in this country; in which, however, there are certain analogies which enable us to group them into one general assemblage. Mr. Lonsdale's paper on the Bath district may be referred to as giving a lucid account of the varieties and peculiarities of these rocks. The oolitic limestones are well known from their common use as building materials under the names of Bathstone, freestone, &c. They are intermingled with limestones which do not possess the oolitic structure, and with arenaceous and argillaceous beds. *Lias*, the lowest member of the series, is an argillo-calcareous deposit, commonly containing numerous organic remains.

In England, this formation extends from the sea coast of Dorset, near Bridport, to the northern extremity of the Cleaveland Hills, in Yorkshire, in one range of hills, broken by the vale of the Humber. The lias is often bituminous, and is impregnated with sulphate of soda, sulphate of magnesia, and common salt: it abounds in ammonites, belemnites, and other chambered shells; and in bivalves, and some univalves; gryphites (a deeply incurved bivalve), encrinites, and pentacrinites, and other zoophites; and the remarkable saurian animals already noticed.

To the rocks enumerated under the general term of the *oolitic group* there succeed a series of sandstones, which from their prevailing colour are generally known as the *red* sandstone and marl formation, and which are incumbent upon the coal deposits of this country. Their organic relics are numerous; and they derive interest from being the seat of our great beds of salt, which occur in the counties of Cheshire and Worcester.

In the salt itself there is nothing very remarkable, except, perhaps, its occasional purity. It is sometimes colourless, and contains not more than 2 per cent. of foreign matter; in other parts it is tinged red, and more or less mixed with earthy impurities. The *brine springs*, which often yield 20 per cent. of salt, are doubtlessly derived from the accession of water to similar solid masses.

How the salt came where we now find it, is a question of no easy solution. It has been supposed that it was produced at the bottom of salt-water lakes, and the existence of beds of salt in certain lakes of Africa and South America is quoted in favour of such an hypothesis.

Another substance abundant in this formation, and apparently more or less connected with the salt deposits, is gypsum, or sulphate of lime; known, also, under the name of alabaster. It has been already mentioned as occurring in the tertiary strata, forming the cement which entombs the organic remains of the Paris basin, and where it was probably formed by sulphuric exhalations and springs acting upon the detritus of the secondary chalk, which there appears to have suffered such extensive degradation.

In our red-sand districts the salt and gypsum are distinct, but they are not unfrequently mixed; and in Egypt a highly saline gypsum is sometimes used as a substitute for salt. This rock, when exposed to air and water, would of course lose its more soluble common salt; and hence, probably, the scriptural and oriental allusion to the inefficiency of *salt* which has lost its *saltness*.

In the north of England, magnesian limestone is associated with these strata. It is usually of a yellowish or fawn colour, not abundant in organic remains, and is often a valuable and durable building stone.

The next substances which occur in descending order are the *coal strata* or *measures*, or *coal basins*, as they are sometimes called; and if, upon our journey downwards, we have been struck with the extraordinary aspect of the *animal* kingdom at certain periods or epochs of the earth, we shall now meet with matters quite as wonderful in the remains of *extinct vegetable tribes*, while at the same time we have brought before us a substance of such importance to our commercial welfare and national resources, that every trifle connected with its history assumes an air of peculiar and distinct interest.

There are two or three points, and those of much theoretical importance, respecting the origin of coal, in which geological authorities seem nearly unanimous. The one is, that our present coal is exclusively of vegetable origin, formed apparently from the destruction of vast forests; and from the prodigious quantities of timber drifted by some of the great rivers of the world into the present ocean, it is by no means improbable that a similar formation is now going on in the depths of certain parts of the sea: and, secondly, from the nature of the preserved vegetables, it would seem that the climate of these parts of Europe *was* of a tropical character. It may also be inferred that these strata were deposited in the neighbourhood, and often probably upon the verge, of extensive tracts of dry land; for the trees that are found in coal strata are often like those of our submarine forests, or of the Portland dirt-bed, as far as position goes; and, finally, that they were afterwards elevated, and often singularly dislocated and contorted by forces, the nature of which we shall afterwards consider.

In some coal fields there are appearances which justify the term *coal basin;* they are of limited extent, frequently dip as it were to a common centre, and consist of various beds of sandstone, shale, and coal, irregularly stratified, sometimes mixed with conglomerates,—the whole showing a mechanical origin.

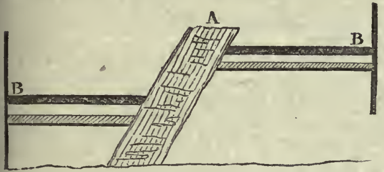
That these depositions have taken place, and that the change of the wood into coal has often been effected under great pressure, and often under pressure and heat, seems evident from the appearances of some of the vegetable masses, and also from the manner in which the carburetted hydrogen escapes in the form of *blowers* from the strata; as if it were pent up in their cavities under vast condensation, and sometimes perhaps even in a liquid form.

An opinion respecting the origin of coal, first advocated by De Luc, and more recently by Adolphe Brongniart (the celebrated fossil botanist), is, that coal beds have been extensive sheets of vegetable matter, resembling in that particular *peat bogs*, which have, one after the other, been submerged and covered by sand and silt. There are numerous facts in favour of this view, which has also been sanctioned by Mr. De la Beche, as, upon the whole, more consistent with the phenomena presented by coal formations.

It has been well observed by one of the most instructive geological writers, that in the present condition of the coal measures we have opportunities of observing design, even where things are so disposed as at first sight apparently to preclude any such inference. The accumulation of vegetable matter at a remote epoch in the history of the world, for the convenience and consumption of creatures which were long afterwards to exist upon its surface, must strike the least inquiring; but when the twisted, dislocated, upturned, and broken strata so common in the coal districts are before us, the design appears to the superficial observer to be frustrated, especially when the miner complains of them as interrupting or even preventing his progress; so that this apparent confusion has sometimes been regarded as a bar to the ingenuity and industry of man in extracting the combustible so valuable and requisite. When, however, we contemplate the subject more closely, we find that these very irregularities and inconveniences are in reality highly advantageous, for they often heave up seams of coal that would otherwise be beyond reach; and they perform the yet more important service of excluding the passage of subterraneous waters from one part of the workings to another: so that the miners in collieries situated in one particular mass have only to contend with the waters in it; whereas if the strata were always unbroken and continuous, such would be the abundance of water flowing into the workings that the utmost difficulty and expense would be incurred in proceeding, and it would often be necessary altogether to abandon the further extraction of the coal. The section of strata in Jarrow colliery, near Newcastle, shows how curiously they are sometimes fractured and dislocated; and in the coal measures at Little Haven, St. Bride's Bay (Pembrokeshire), we have a good instance of their occasional contortions.

The annexed diagrams represent a section of a coal basin, and the disturbance and dislocation of the strata by dykes or cross-courses. A A, in the first figure, are the dykes by which the shales and coal, B B B, are disturbed; and, in the second, the seam of coal B B,

which, as in the other case, was once continuous, has been dislocated by the intrusion of the dyke A.



Though there may be many beds and seams of coal in one field, it is seldom that many of them are worked; they are generally of uniform thickness through a great extent, but are sometimes subject to irregularities. When less than two feet thick, they are seldom worked to any great extent.

The nature of the upper stratum of stony matter, or *roof*, is very important. If compact, it is secure from falling, and keeps out water; if loose, the expense incurred in supporting it absorbs the profits of the coal. The deepest coal mines of England are those of Northumberland and Durham, which are worked nearly 1000 feet below the surface. The thickest bed of coal is said to be at Wood Mill Hill colliery in Staffordshire, and to exceed 40 feet. From 6 to 9 feet is the average thickness of the most productive seams.

Coal strata are often accompanied by *clay ironstone;* an ore of iron not so rich in metal nor so pure as many others, but which has acquired infinite importance from its association with coal and limestone, the substances which are requisite to reduce and purify it. The richest varieties of this ore are said to yield about 25 to 30 per cent. of metal, and it is the chief source of the enormous quantities of iron manufactured in this country.

§ II.

Mountain Limestone, which is the next rock in descending order, may be considered as forming the foundations as it were, or basins, in which the coal is commonly deposited, and in this respect bears some correspondence to the chalk and its tertiary formations.

This kind of limestone is of various colours, and often so full of organic remains as to appear almost entirely made up of them, especially of encrinal columns; but sometimes scarcely an organic relic is to be detected, and it is veined and variegated with streaks of calcareous spar. Both these varieties form useful and often handsome marble.

This rock is of further interest, as being that which in the centre and north of England is the seat of our most productive lead mines; hence it is called *metalliferous limestone*. The great patch of limestone extending from the Tweed to the Tees, bounded by the coal measures on the east, and on the west by the Cheviot Hills, is especially known as the *lead measures*. The characters of the rocks are very variable. The veins hitherto worked occupy a space of about 15 miles north and south, and 20 west and east, and run, with little exception, nearly west and east.

The Yorkshire limestone district, exclusive of its metallic veins, is traversed by others, which, as they are only filled with lapideous substances, are of little interest to the miner, but of deep importance to the geologist. They often intersect the metallic veins, disturbing the parallelism of the strata, and often occasion much irregularity and confusion. There is here an instance of the elevation of the strata to more than two fathoms upon the side of one of these cross veins. The contents of these cross courses are very miscellaneous; and where the material they are filled with is much harder and more durable than the assailed strata, their course is often perceptible upon the weather-worn surface of the country which they traverse. Such is the cross vein of the lead measures called the Devil's Backbone, forming a ridge that may be traced a considerable distance along the country through which it passes.

The Derbyshire limestone district is well known, and frequently visited on account of the romantic scenery and wonders in which it abounds. Castleton is its northern point, and it extends southward about 25 miles to Weaver Hill. Its breadth is very irregular, but nowhere exceeds about twenty miles. Its eastern end contributes to the delightful and varied scenery of Matlock, and its north-western extremity is celebrated for the wonders of the Peak.

In regard to the varied aspect of this district, it may be observed that the different strata of limestone differ considerably from each other; that beds and dikes of another species of rock intervene, provincially called *toadstone;* and that the respective edges of these strata come to the surface; and, lastly, that the country is traversed by a great fault or dislocation.

The singular turreted and broken appearance of these limestone rocks, and the fantastic shapes which their various masses occasionally assume, are well seen in Dovedale; and some of their other peculiarities, especially their curvatures, and some of the dislocations which they have suffered, are evident in Matlock and its neighbourhood. In the High Tor the stratification appears horizontal and regular when viewed in front; but a more accurate examination shows that it is curved and irregular: a section made by the river Derwent, near the toll bar, well illustrates this peculiarity. Another instance of *curved* strata may be seen in Crich Cliff, about 4 miles east of Matlock; it is an isolated hill about 900 feet above the level of the river. According to Mr. Bakewell the mass of the hill consists of arched strata of limestone. The different beds of limestone are of very different qualities and composition; the upper cherty, and often bituminous, abounding in corallites and encrini, &c., often curiously seen in relief upon its weather-worn surface. Beneath the rock contains beds of magnesian limestone and silicious limestone or dunstone, and towards its lower parts beds of black marble. The lowest limestone stratum is that which forms the Peak Forest, the downs of Buxton, and the Weaver Hills; and in it are several remarkable caverns. Here also we find at Castleton those curious nodules of fluor spar celebrated for the manufacture of vases, &c.; also that very singular mineral, the elastic bitumen, or fossil caoutchouc. The subterranean streams which traverse many of these caverns, the *stalactites* and *stalagmites* in which they abound, and the thermal waters which characterize the district, are all important points to be noticed. The toadstone of Derbyshire is sometimes represented as regularly stratified between the limestone beds, but this requires further investigation; and at all events the beds, if such they are, are liable to many extraordinary irregularities. The toadstone never contains shells or organic remains; calcedony, zeolite, and globules of calcareous spar are not uncommon in it; and whatever theory may be entertained in respect to it, it evidently bears the character of a formation distinct from its associates. In the cave at Castleton it forms a large irregular column, having the appearance of the rock called basalt.

The veins in the limestone in Derbyshire contain the ores of lead, manganese, copper, zinc, and iron: the proper repository of the lead appears to be the limestone, though it also occurs in some other strata, and rarely in the toadstone, in which it is always in small quantities, and merely in strings or very imperfect veins. Near Bristol the limestone hills rise from below the red sandstone, and form the edges of the coal basin. In some places it is very bituminous, as on the Avon at Chepstow, and even exudes petroleum. On the Welsh coast of the Bristol Channel we have another ridge of limestone, forming the basin, as it were, in which the great coalfield of South Wales is situated. The hills on the west of Swansea and the cliffs on the south of Pembroke are of this formation; and again on the banks of the Wye it constitutes scenery of a soft but most romantic character. There is something singularly fascinating in the landscape of the limestone districts, resulting not only from the varied forms and groupings of the mountain masses, but depending also upon the nature of the substance, and of the soil derived from its decay. Upon the perpendicular and projecting precipices lichens of various and singular hues alternate with the grey surface of the uncovered rock; a variety of shrubs are scattered by nature's hand upon its picturesque and waving sides; ivy and other creeping plants issue in gay luxuriance from its crevices, and the glens and valleys are adorned by every variety of verdure.

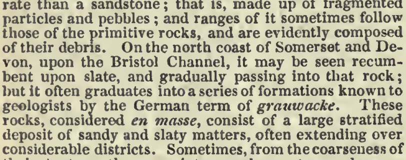
We may now cast a glance upon the probable state of the globe at the period at which the coal and the subordinate limestone rocks were formed. In regard to the latter it would appear that they extend over a great part of central and northern Europe; and that rocks containing the same organic remains are found in the lake district of North America, and are even abundant upon the borders of the Arctic Sea. The great quantity of corals found in this formation, as well as its vast extent, seem to prove that it was formed in a deep and extensive sea, in the midst of which there were many isles. These isles were apparently composed of primary and of volcanic rocks, which being exposed to the erosive action of torrents, to the artillery of the waves, and to superficial

decomposition, supplied materials for the pebbles, sand, and shale, which, together with substances introduced by mineral springs and volcanic eruptions, contributed the inorganic parts of the carboniferous strata. In regard to the fossil remains of these strata, the vegetation of the coal districts is stated by botanists to possess the characters of an insular and not of a continental flora; and we may suppose the carbonaceous matter to have been derived from trees swept into the sea by torrents, and from peaty matter, which even in our climate often blackens the rills of marshy grounds. It has been acutely observed by Mr. Lyell, that if we seek for present points of analogy to this state of things, we must either turn to the North Pacific, and its numerous submarine or insular volcanos between Kamschatka and New Guinea; or, in order to obtain a more perfect counterpart to the coralline and shelly limestones, we may explore the archipelagos of the South Pacific between Australia and South America, where coral reefs, consisting in great part of compact limestone, are spread over an area not inferior perhaps to that of our ancient calcareous rocks, though we even suppose these to be prolonged from the North American lakes to central Europe.

In these remarks we anticipate a subject requiring more full discussion, and they are merely introduced here to direct attention to the coincidences and analogies between the present order of things produced by causes now active and by the ordinary proceedings of nature, and those great but remote changes of the earth's surface often unnecessarily referred to extraordinary catastrophes and convulsions.

Beneath this great limestone formation strata of sandstone occur, which from their position, as opposed to those *above* the coal, are known under the name of the *old red sandstone.* It often appears more as a conglomerate than a sandstone; that is, made up of fragmented particles and pebbles; and ranges of it sometimes follow those of the primitive rocks, and are evidently composed of their debris. On the north coast of Somerset and Devon, upon the Bristol Channel, it may be seen recumbent upon slate, and gradually passing into that rock; but it often graduates into a series of formations known to geologists by the German term of *grauwacke.* These rocks, considered *en masse*, consist of a large stratified deposit of sandy and slaty matters, often extending over considerable districts. Sometimes, from the coarseness of their texture, they pass into *conglomerates;* and sometimes, from its fineness, graduate into *roofing slate*, apparently formed of highly comminuted detritus. In this formation the sandstones are comparatively deficient in organic relics, but they abound in the limestone. Upon the whole they exhibit marks of *slow* deposition. This series of rocks, namely, the formation intervening between the mountain limestone and the inferior granitic or hypogene rocks, has been ably investigated by Mr. Murchison, who has assigned to them the name of *Silurian*, from their being best developed in that part of England and Wales formerly included in the ancient British kingdom of the *Silures.* The lower part of the Grauwacke series constitutes the Cambrian rocks of Professor Sedgwick.

There are some curious facts respecting the stratification of the slaty portions of these rocks, which, as they apply to slate generally, it may be proper here to mention; and as an illustrative instance, that noticed by Mr. De la Beche as occurring at Bovey Sand Bay, on the east side of Plymouth Sound, may be referred to: *a a*, *curved* beds



of slate, the laminæ of which meet the apparent lines of stratification at various angles, being even perpendicular to them. The beds are cut off by the fault *f* from the slates *c*, the laminæ of which are confusedly horizontal. The whole is covered by detritus of fragmented slate *b*.

We are now gradually descending into the *non-fossiliferous* rocks; for the lower grauwackes graduate into slates destitute of organic remains, and into rocks of chemical rather than of mechanical origin. Thus we arrive at that very remote condition of our planet, when neither animal nor vegetable life seems to have existed on its surface; and instead of wandering in imagination amid forests, lands, and seas, surrounded by strange vegetables, and by animals yet more strange, our attention must be directed to the laws which govern inorganic matter.

Of these *inferior*, *stratified*, and *non-fossiliferous* rocks, one of the most abundant and important is *argillaceous* or *clay slate.* It differs in texture and composition; and except from its geological position, is often scarcely distinguishable from the slates of the grauwacke series. When chlorite prevails, it is called *chlorite slate;* and it passes into *hornblende slate*, and into *mica slate*, and is associated with *quartz rock.*

The origin of these rocks is extremely ambiguous. In regard to clay slate, it is apparently a mechanical deposit of very finely comminuted matter. It often contains regular crystals of pyrites: it is of various colours, generally grey, black, or reddish, and like most other rocks derives its colours from the oxides of iron. Beds of this slate, when finely lamellar, are valuable, as furnishing materials for roofing. Those which are least absorbent of water, and which split into the thinnest and smoothest plates, are selected; but they should not be *too thin*, as they then fail in durability, and do not resist the force of storms. Slate is also largely employed for other architectural purposes, and for the construction of tanks and cisterns. In this country there are extensive quarries in Westmoreland, Yorkshire, Leicestershire, North Wales, Cornwall, and Devonshire.

The forms, tints, and general associations and outlines of some of the mountains of Cumberland especially, and the English lake scenery in general, are illustrative of the mountains of the grauwacke and slate formations. The former exhibit united softness and grandeur; the latter a more elevated and rugged aspect. We have varied and grand instances of slate in the mountainous district of North Wales, and in Cumberland and Westmoreland. The cluster of hills, of which Skiddaw forms the highest elevation, may perhaps be referred to as genuine clay slate; and in Devonshire and Cornwall the granitic range, which traverses the promontory like a backbone, beginning at Dartmoor and terminating at the Land's End, has slate overlying it on both sides. The scenery of Fowey, Looe, Tintagel, and other places on the north and south sides of Cornwall, derives its grandeur and charms from the various assemblages of slaty headlands, promontories, creeks, and islands. Sometimes its strata jut out in bold fantastic forms upon the ocean, and sometimes gradually shelve away into gentle slopes. Their verdure is usually scanty and uncertain; but here and there a clayey soil finds a resting place, and cherishes patches of shrubs interspersed with trees of loftier growth, and attracting attention by the sterile and fragmented surface which often surrounds these insulated spots. The beauties of the coast of Cornwall are singularly contrasted by the barren exterior of its central road and great mining district; where scarcely a blade of grass relieves the black and sombre hues of the ground, but where heaps of rubbish, once rich in embowelled treasures, give a gloomy irregularity to the surface; and where the ponderous heaving of machinery raises subterranean rivers to a new level and into new channels, and enables the miner to arrive at treasures which but for the inventive genius of Watt would have remained inaccessible.

The mountainous aspect of slate is seen to great perfection on the western side of Wales; where Snowdon, Plynlimmon, and Cader Idris, with many of their respectable associates, present the peaked summits, the dark and narrow valleys, the steep precipices, and the fragmented slopes that peculiarly belong to this formation.

Associated with the rocks of the inferior stratified group (slate, mica-slate, gneiss), there are those beautiful varieties of white and crystalline limestone known as the statuary marbles of Greece and Italy. They vary in their texture. That of the lake of Como, which is the building stone of Milan cathedral, is a good instance of coarse-grained marble; and sometimes it acquires a slaty fracture from the admixture of mica or talc, and passes into *dolomite* from the presence of magnesia.

Before we quit these rocks, there is one remarkable feature which belongs to them and others, and which may now be adverted to, though its *cause* will perhaps be more evident hereafter; namely, the singular contortions to which they are subject. The strata of slate, for instance, are often waved to a greater or less extent; and sometimes an entire bed affects a serpentine irregularity, which gradually merges into a straight line above and below. These contortions are sometimes, to all appearance, independent of any other kind of rock. Sometimes they are apparently caused by veins of a granitic, porphyritic, or basaltic character, invading the slate as it were from below, and bending it into various irregularities, or sometimes merely dislocating and breaking its strata: as if, in the one instance, it had acted upon soft, yielding, and unconsolidated matter; and in the other, as if it had been violently protruded into the surrounding strata of an already hardened mass. These contortions are not peculiar to the slaty rocks; they may also be seen in the newest and in the oldest formations, varying infinitely in their forms and dimensions. They have sometimes misled geologists as to the relative positions or conformity and nonconformity of alternating rocks; so that it requires great care, though at first sight it may appear extremely easy, to determine whether one rock rests on the upturned edges of another or not.

In taking leave of the stratified rocks, we lose sight of

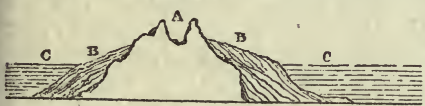
that regularity of superposition which is of so much use in assigning to them the periods of their formation, and which, in conjunction with their organic remains, affords such important evidence respecting their relative ages, and the circumstances of climate under which they have been deposited.

Their minute examination shows the caution with which certain theories connected with them require to be received. The gradual transitions of one kind of rock into others on the one hand, and their sudden and abrupt lines of demarcation on the other; their verticality in one place, and their horizontality in others; their occasional resemblances and frequent dissimilarities, are circumstances which will lead the unprejudiced observer to receive all geological hypotheses with the utmost circumspection. Another important point relates to the dissimilar texture and contents of rocks appertaining to the same series, but occurring in different situations and countries: thus the *equivalent* of our chalk is a granular limestone in part of the Alps; and here, as in other cases, it is the identity of the organic remains that determines the geological era.

We have now then arrived at the crystalline, massive, and unstratified rocks, which seem to form the bases or foundations upon which the others have been deposited. They have therefore been called *primary* or *primitive rocks;* and as they are destitute of organic remains, they were regarded at one time as of more ancient origin than the superincumbent strata. But the progress of inquiry has led to a very different view of the origin and antiquity of these rocks; and modern geology, in assigning to them an igneous origin, assumes that though they have been formed at different epochs, they are often of more recent production than the older stratified rocks, and even sometimes of a date subsequent to those depositions which form the tertiary series.

Upon this subject the theories of M. de Beaumont have excited much attention. He assumes that the different mountain chains of the world have been thrown up at different geological periods; that each great chain runs in a certain uniform direction; and that their relative dates of protrusion may be ascertained by their effects upon the sedimentary strata. If, for instance, we find the great mass of crystalline rock on all sides surrounded by tranquil and horizontal sedimentary deposits, we infer the deposition of the latter *subsequent* to the former. But if we find the sedimentary deposits *upheaved* by the crystalline rocks, we then infer the posterior date of the latter; and if other horizontal sedimentary deposits lie upon the upraised series, another geological date is obtained as respects them.

The following diagrams will perhaps assist the illustration of De Beaumont's theory. A may represent a chain of granitic rocks; and B, C, and D the incumbent rocks or strata. From the dislocated and inclined position of B, and the horizontal and undisturbed state of C, it may be presumed that the chain A was elevated subsequently to the existence of B B, but before the deposition of C C. On the other hand, in the lower figure, C C have also been elevated, whilst D D are undisturbed; whence the inference that in this diagram the chain A is of a later date: here D D represent the undisturbed or horizontal deposits.



Reasoning upon such grounds, it has been attempted to prove that the great mountain chains of the earth are of various dates, some formed prior to and others subsequent to their secondary or sedimentary neighbours. Thus also, if we assume that these great crystalline masses have been thrust up from below, may we account for the elevation of rocks abounding in organic remains. Whether these mountains have been *suddenly* or *gradually* upheaved, is a very important point in controversial geology. The one opinion has been advocated by De Beaumont, the other by Mr. Lyell. According to De Beaumont, there have been long periods of repose in the history of the earth, during which the deposition of sedimentary matter has gone regularly on; and there have been short periods of violence, during which that continuity was broken by the sudden formation of great mountain chains. It is supposed that all the chains thrown up by a particular revolution, or at one time, are nearly parallel; but that those thrown up at different periods have different directions, so that they sometimes cross each other: that, therefore, there has been a recurrence of these paroxysmal movements from the remotest geological periods; and, of course, that they may still be reproduced, and break the present repose of our globe. It is presumed that the latest of these revolutions (even within the historical period) was that which upraised the Andes, for that chain is the best defined and least obliterated feature in the present exterior configuration of the globe; and as the instantaneous appearing of such enormous mountain masses must have caused a prodigious agitation in the waters of the ocean, it is probable that a deluge was one of its effects; and, lastly, as common volcanic powers are apparently inadequate to these successive revolutions, they are assumed to depend upon the secular refrigeration of the interior nucleus of our planet causing a fracture of the outer crust, and the consequent spirting out, as it were, of some of its interior contents.

There is much that is imposing, and to all appearance satisfactory, in parts of this bold theory; but the question is, how far is it strictly consistent with facts? Have we any evidence of such frightful convulsions? are they consistent with what we actually know of the earth's structure? are they in accordance with present phenomena? or can we frame any other theory equally applicable, and less at variance with the changes now in progress, and with the known causes of those changes? These are questions which Mr. Lyell has directed himself to, and which involve the effects of existing volcanos, and of various causes of decay and reproduction that now affect the surface of the earth, and to which we shall allude afterwards: they are discussed at length in his valuable work which we have already so abundantly quoted — his *Principles of Geology*.

Proceeding in the retrospective survey of geological monuments, from those of recent to those of more ancient date, we have traversed a series of strata, each characterized by their relative positions in respect to the others, but more unequivocally distinguishable into regular epochs of formation by their organic relics. These we have found gradually to diminish, and ultimately to disappear; the rocks slowly losing their sedimentary character, and appearing as crystalline aggregates, and consequently as products of chemical rather than of mechanical action.

The formations at which we have now arrived include granite, and its associates greenstone and basalt; and from these more ancient substances we pass by regular analogies to a variety of evidently volcanic products, — some of remote antiquity, others formed within the historical period. How this interesting series of rocks are thus connected into one group, and what the evidences are of their igneous origin, will appear presently.

As they form the basis upon which the sedimentary rocks appear to lie, rising to the surface in the central and highest parts of the great mountain chains, and at the same time passing down and forming the inferior parts of the crust of the earth, they were once, as already stated, called *primitive rocks*, and regarded as having been formed anteriorly to the others; but the more close examination of their relations to the sedimentary deposits just adverted to, and of the changes which they have effected upon them, have induced modern geologists to reject such an hypothesis, and to consider them as of a later date; varying, however, in this respect among themselves, and hence divided into *ancient* and *recent* groups, or *plutonic* and *volcanic* formations.

To represent the great mountains of the world, — the Alps, the Andes, and the Himalayan chains,—as upheaved in a liquid or semifluid state from below by processes analogous to those exhibited by the volcanos and earthquakes of present times, has been by some regarded as a bold but improbable conjecture, and as outreaching in improbability many of those theories which have been unanimously condemned as absurd and insufficient. But when we carefully compare the nature of the rocks which compose them, and their influence upon those which they invade and elevate, and examine the vast powers of existing volcanos, the enormous quantities of matter which they have ejected, the force with which they act, the upraising power of earthquakes as manifested within the historical period, and their evident connection with volcanic phenomena, and more especially when these forces are considered as operating under the great pressure of a superincumbent ocean, we find a connected series of facts and analogies which justify the conclusion. We may here examine the rocks in question, and the evidences which they bear of a distinct formation; reserving the history of contemporaneous volcanic phenomena, and of the effects of earthquakes, for a subsequent section.

The first circumstance which strikes us in these formations is the height to which they tower above the sedimentary rocks. In Britain, Ben Nevis and Cairngorm, in Inverness-shire, are between 4000 and 5000 feet above the level of the ocean; Mont Blanc is between 15,000 and 16,000 feet above the same level, and is the highest

mountain in Europe; Soxate, the highest summit of the Andes, from 24,000 to 25,000; and the highest peak of the Thibet chain, 26,000 to 27,000 feet.

Under the term *granitic formation*, we may include not merely granite (which is a crystalline aggregate of quartz, felspar, and mica), properly so called, but other rocks into which it merges, either from the predominance of one or other of its ingredients, from the loss of one or other of them, or from the occasional addition of some new mineral. We may also include in this division of rocks those substances which are their occasional accompaniments.

When mica abounds, granite passes into *gneiss;* and when the felspar is nearly or altogether wanting, it forms *mica slate;* and this again often passes into *quartz rock* from the scantiness or absence of mica. These would seem to be sedimentary rocks gradually passing into granite. They may be traced upon the one side into clay slate, and into granite on the other. *Hornblende*, which is an alumino-silicious mineral containing magnesia, and abundant in black oxide of iron, forming prismatic crystals, is often intermixed with granite, and sometimes with felspar only, forming *sienite* and *sienitic rocks;* and when crystals of felspar are as it were embedded in massive felspar, the rock is called *porphyritic* or *porphyry*.

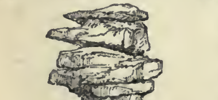
The presence of granular or crystalline marble amidst these rocks has already been mentioned. Respecting its source, there is room for difference of opinion; but it possibly may have been fossiliferous limestone, the organic relics of which have been destroyed by the heat which conferred upon it its semicrystalline form: and it has been proposed to account, upon the same principle, for the absence of organic relics in the slaty rocks of this series.

Serpentine is a rock which it is somewhat difficult to define. Hornblende, schiller spar or diallage, and felspar, and perhaps also talc, appear to be essential to its constitution, and sometimes they are distinctly visible; while at others the rock is so fine-grained as to be nearly homogeneous. Its variety of colours (whence its name) recommends it for ornamental purposes, but it is too soft to admit of a permanent polish. *Talc* forms inelastic laminæ, soapy to the feel, and differs little from *steatite*, which often pervades serpentine in veins.

Such are the varieties of the granitic group; the *hypogene rocks* of Lyell (from *ὑπο*, *under*, and *γινομαι*, *I am formed*), that is, nether-formed rocks: he calls the stratified rocks of this class *metamorphic*.

The largest granite tract of England is that of Devon and Cornwall, where its sides are covered by slate, but where it rises in several places to the surface; it also forms the rocky promontory of the Land's End. There is here nothing either picturesque or sublime belonging to the granite formation. Dartmoor appears the head quarters of dreariness and desolation, forming a large mountain tract of nearly 80,000 acres in extent, strewed with boulders and fragments, and appearing to set cultivation at defiance. This granitic district is nowhere of any considerable elevation; its highest point, near Okehampton, is 2070 feet.

The peculiarities of the West of England granite are best seen at the Land's End, where a large patch of it protrudes in a wedge-shaped promontory. It appears formed of fragments and masses placed upon each other in the rudest disorder, and sometimes in fantastic piles and insulated blocks, which, though arising from the peculiar manner in which the rock is decomposed and dislodged by the weather, have been mistaken for Druidical remains. These *tors*, as they have been called, have been described by Dr. M'Culloch (*Geol. Trans.*), and some of them are depicted in the engravings annexed to his paper. One, called the *Cheesewring*, near Liskeard, consists of five blocks, of which the upper are larger than the lower, the whole pile being about 15 feet high. The stones composing this and other similar piles suffer by the action of the weather most rapidly upon their edges and angles, which gradually become rounded, and the blocks then begin to totter and ultimately fall. This tendency of square blocks to become spheroidal, and which has sometimes been mistaken for the effect of friction, shows that attrition and transportation by streams are not always essential to their rounded appearance. The celebrated *Logging-stone* well exhibits the tendency of this kind of granite to cuboidal separation. Some of the Shetland Isles present magnificent specimens of the wear and tear of granite. On the west of Meikle Roe the softer veins have mouldered away, while the firmer rock which included them has remained unaltered; and in this way long narrow ravines are laid open which give access to the waves. The singular cluster of rocks at Hillswickness,



Cheesewring.

Hillswickness.

which has been compared, when seen at a distance, to a small fleet of vessels with spread sails, also affords a good instance of granitic disintegration on the one hand, and of its permanence on the other; weathering storms and an ocean which would long ago have consigned softer materials to utter destruction.

There are, however, some varieties, which decay with comparative rapidity. De Luc talks of the *friable granite* of the Hartz, and Saussure describes the mouldering down of that of the Alps. The waters of the Arve are rendered turbid by the pulverulent felspar that comes from the *Aiguilles de Chamouny* and other points that border the *Mer de Glace*. The road across Dartmoor from Ashburton to Chagford traverses, in one place, such loosely compacted granite as to resemble a bed of gravel. The granite of the Carglaise mine, near St. Austle, is so soft and pulverulent, that the excavation might almost be taken for a chalk pit; and in the same vicinity the immense quantities of white porcelain earth, as it is called, is of similar origin, and apparently derived from the perishable nature of the felspar, which, giving way, suffers the grains of quartz and mica to fall out. Chemical analysis points to the loss of the alkali of the felspar as the cause of this extreme proneness of some kinds of granite to decay. Independent, however, of chemical composition, mere mechanical texture and the general aggregation of mountain masses have much to do with their relative durabilities. When the arrangement of granite resembles that prevalent in the greater part of Cornwall, water gradually penetrating between the blocks and masses freezes there, and thus slowly removes or transfers them to unstable ground; while the more solid texture of other varieties of granite, denying the access of water to its fissures, is slower in suffering the decay referable to that powerful cause.

Gneiss and mica-slate often form mountain masses in association with each other and with the varieties of granite. The former is seen singularly contorted upon the coast of Lewes; and mica-slate rock is associated with the serpentine of Cornwall, and is seen in great perfection among the Scotch granitic scenery, more especially in the vicinity of Dunkeld, and in extraordinary magnificence in the lofty mountain of Benmore. Ben Lawers, on the north of Loch Tay, and many of the neighbouring mountains, furnish highly instructive specimens of granite passing into gneiss, mica-slate, and chlorite-slate. About three miles south of Dunkeld, a stratum of grauwacke is seen incumbent upon chlorite-slate, gradually passing into a fine gray roofing slate, and this recumbent upon mica-slate. The peculiar and differing dip of the respective strata, the singular manner in which they are pierced and traversed by veins of felspar and quartz, and their association with micaceous iron, are circumstances highly interesting in respect to the origin of hypogene rocks; and the beauty and magnificence of the district in regard to scenery is not less than its diversified geological peculiarities.

Mica-slate, abounding in garnets, and often sprinkled with red patches originating in their decomposition, and becoming sienitic from the interspersion of hornblende, is prevalent upon the banks of the Tay and about Dunkeld; but it is in Glentilt that the geologist, both practical and theoretical, will find the most ample materials for the study of the association and junctions of this series of rocks.

In the immediate neighbourhood of Blair, the Tilt exhibits upon its banks a section of the rocks forming its bed; and the micaceous strata here and at the falls of the Bruar incline nearly at the same angle to several points of the compass, giving a curious confusion and interweavement to their assemblage. Ascending a few miles up the glen we observe granular limestone in the midst of the granite, which sends forth so many veins as to *reticulate* the slate; and often there appear to be detached fragments of granite in the limestone and shistose rocks.

There are other places in which analogous peculiarities of granite and its associates may be observed; for instance in St. Michael's Mount, upon the south coast of Cornwall, where the granite not only graduates into mica-

slate, but the latter is traversed by granite veins, which appear to break and indurate it. Exclusive of Cornwall and Devonshire, the hypogene or plutonic rocks are comparatively rare upon the surface of England. The Malvern Hills, Mount Sorrel in Leicestershire, and a few of the ridges of Cumberland and Westmoreland, afford specimens of these rocks. In the Isle of Man and in Anglesey granite is associated with clay-slate; and near Gwindy in Anglesey the points of granite curiously protrude from beneath the slate.

In reference to the origin of granitic rocks, it appears almost impossible to reject that theory which regards them as having been formed by the igneous fusion of sedimentary rocks; while it cannot be denied that peculiar circumstances must have conspired in conferring upon these formations their distinct and peculiar characters. Their analogy to basalt, greenstone, and trap will presently be noticed, and the close resemblance of the latter to existent and contemporaneous volcanic products traced out. But then why is not granite formed by our present volcanos? or why are more modern lavas so distinct from these ancient rocks? The probable cause of the difference lies in the circumstances under which the subterranean fusions have been effected; in the case of granite, probably under *great pressure*, and out of the contact of air and water. What is now going on at great depths, and under the pressure of fused masses and a fathomless ocean, it is impossible actually to ascertain, and analogy only can guide us; but the circumstances just mentioned appear essential to the formation of highly crystalline rocks, and the extremely slow cooling of these fused masses would also favour many of their peculiarities. In demanding this liquefaction and gradual refrigeration the plutonic geologist has often been sneered at for the exorbitancy of his postulates; but the great length of time which lava streams require to cool, even in the open air, justifies the conclusion. The melted matter poured out of Jorullo in Mexico, in 1759, which accumulated in some places to the height of 550 feet, retained a high temperature for fifty years after the eruption. For what immense periods then may not great masses of subterranean lava remain red hot, and how gradual must be the process of their refrigeration! This process, indeed, may be retarded for an indefinite time; for the lava in the crater of Stromboli has been in a state of constant ebullition for the last 2000 years, and this mass of fused matter must of course communicate with some great reservoir below. In the Isle of Bourbon also, where there has been an eruption every two years for a very long period, the lava below must be in a state of permanent liquefaction. In adverting to the effects of long-continued fusion upon earthy and alkaline compounds, and to the various textures and characters of rocks which may thus result from the liquefaction of similar materials, sometimes producing distinct crystalline aggregates, at others more homogeneous products, we are sanctioned by the result of actual experiments; and although our artificial products are necessarily formed upon a scale of trifling insignificance as compared with the natural ones, we sometimes obtain extraordinary and unexpected results — to such an extent, that it is impossible by any *à priori* reasoning to determine what new mineral products may not be obtained by the varied effects of heat upon components little dissimilar.

When, therefore, melted matter is injected into the fissures of a contiguous rock, it may either cool *rapidly* if that rock had not previously acquired a high temperature; or if it had, it may continue for centuries at a high temperature, and consequently attain various textures, and present a variety of distinct minerals.

We have already stated what our means are of judging of the relative ages of these rocks. Some of the granitic chains appear to be of great antiquity, antecedent to the secondary and tertiary rocks; though perhaps there may be a few cases in which they are apparently contemporaneous. It is also probable that they are constantly in a state of *production*, perhaps to be upheaved at some future period by operations which we shall afterwards endeavour to unravel.

From granite and its associates we pass to a class of rocks often designated as the *trap formation*, including whinstone, basalt, greenstone, &c. They are apparently of igneous origin, and approach in many instances very closely in their effect and character to the lavas of contemporaneous volcanos.

The term *trap rock* has been especially applied to those *step-like* or scalar declivities which mountain masses of this substance sometimes present. In employing this term, we shall rather use it as a generic name of the rocks in question, than as specifically implying the materials of which they are composed; and since the varieties known under the names of greenstone, basalt, toadstone, whin, pitchstone, and amygdaloid belong to this same class, and often graduate into each other, these terms may be occasionally employed as characterizing individual specimens of trap rock,—designating the fine-grained homogeneous rock *basalt*; the greenish varieties which especially occur among the older rocks, and sometimes approximate to the nature of sienite, *greenstone*; those containing nodules of calc-spar, quartz, agate, zeolite, &c., *amygdaloid* or *toadstone*.

The general character of these rocks is, that they appear amongst stratified deposits of all dates, and among the oldest and newest rocks: sometimes graduating through greenstone and hornblende rocks into varieties closely connected with granite; at others degenerating, as it were, into substances closely resembling the lavas of existing volcanos. When they assume a stratified character, it arises from their apparent injection in a state of fluidity amongst other rocks, or from having been subjected to peculiar laws of action whilst cooling; and where they come into contact with other rocks, they often fill their rents and fissures with dikes and veins, and harden or alter them in such a way as to leave indisputable records of their igneous origin, — converting chalk into marble, coal into cinder or coke, sandstone into chert and jasper; and the veins themselves present different textures, dependent on their bulk or breadth, and upon the greater or less rapidity with which they appear to have cooled. The following may be selected as illustrative instances of the aspects, characters, and situations of trap rocks:— Under the name of greenstone it is seen in characteristic masses, associated with the granite, mica-slate, and serpentine of the Lizard Point in Cornwall. Near Kington and Radnor in Wales, it accompanies clay-slate and old red sandstone; and upon the northern side of Snowdon, Plynlimmon, and Cader Idris, coarse-grained, and with regular crystals of hornblende in one place, and in another fine-grained, homogeneous, and even basaltic or columnar. In Derbyshire, under the name of toadstone, this rock is associated with mountain limestone, and with new red sandstone or red marl in the coalfields of the north of England and elsewhere. In Antrim we find it variously blended with the sandstone and chalk, and even sometimes superior to the newest secondary formations. These instances will serve to show the varied *position* of these rocks. In regard to their *aspects*, we observe them in Cornwall forming blocks and masses, not unlike the granite of the county. Sometimes, as in the coalfields, it forms immense walls or dikes, and even axes of elevation; sometimes, as in Derbyshire, it has the *appearance* of stratification. In the Isle of Mull and elsewhere it is massive and amorphous, and in many places it is columnar; of which the coast of Antrim, the island of Staffa, and some parts of Mull furnish such magnificent instances. The Isle of Mull, Ulva, and the Tresharnish Isles exhibit trap rocks and veins in the greatest variety; and the veins of the Isle of Sky are not only remarkable for their singular extent and arrangement, but for the changes they produce upon the rocks they penetrate, and which are of such a nature as to throw some few rays of light upon the most recondite chemical phenomena connected with geology. Two of these veins penetrate the white marble of Strath. At their junction the trap passes into a substance resembling serpentine, and is penetrated by fissures containing steatite; while the marble acquires all sorts of colours and changes in composition, from argillaceous to magnesian, and from magnesian to silicious. In other parts the trap veins exhibit the several varieties of greenstone, basalt, and amygdaloid.

The island of Staffa is one of the most celebrated basaltic monuments of the world: it is about a mile and a half in circumference; and its greatest elevation, which is upon its north-west side, is about 144 feet. Its lowermost bed upon that side is a basaltic conglomerate. The columns are compact and uniform in texture, dark greyish-black interiorly, and rusty brown where exposed to the weather. Amorphous and columnar basalt and a stratum of pebbles foreign to the island form its upper portion. Fingal's Cave is justly considered as the most beautiful of ocean caverns, and owes its existence to the circumstance of the columns being jointed in that place, while their general character is to be without divisions; hence the successful invasion of the waves in this particular quarter. The entrance is 70 feet high, and resembles a Gothic arch; the width 40 to 50 feet, the length 227 feet. Its interior preserves a considerable degree of regularity throughout, its sides being columnar, and in many places broken and irregularly grouped, so as to catch a variety of direct and reflected tints, mixed with unexpected shadows, and producing a picturesque effect which no regularity could have conferred. The sea never entirely ebbs out of this cave, but the broken range of columns which forms the exterior causeway is continued on each side within it. "This cave," says Dr. M'Culloch, "has been frequently described, but no description is adequate to the representation of its varied beauties and singular associations.

Fingal's Cave.

If it were even destitute of that order and symmetry, that richness arising from multiplicity of parts combined with greatness of dimensions and simplicity of style which it possesses — still the prolonged length, the twilight gloom half concealing the playful and varying effect of reflected light, the echo of the measured surge as it rises and falls, the pellucid green of the water, and the profound and fairy solitude of the whole scene, could never fail strongly to impress any mind alive to the wonders and beauties of nature." Mackinnon's Cave and the Boat Cave in the sland are also worthy the traveller's attention.

The Giant's Causeway, and the various promontories of the coast of Antrim, form another basaltic district of great grandeur and interest.

The Causeway itself consists of three piers of columns, which extend into the sea, and are walled round as it were by precipitous rocks from 200 to 400 feet high, in which are several striking columnar assemblages, vertical, inclined, curved, and horizontal, and in some places appearing as if wedged or driven into the surface of the precipice: Bengore, which bounds the Causeway on the east, consists of alternate ranges of tabular and massive with columnar basalt: Pleskin presents several colonnades of great height and regularity, separated from each other by tabular basalt; and at Fairhead there is a range of columns from 200 to nearly 300 feet in height, supported by a steep declivity, which forms a terrace nearly 600 feet above the level of the sea beneath.

Sometimes basalt rises in massive and abrupt rocks, assuming the appearance of an uniform homogeneous substance, and scarcely exhibiting any of that singular tendency to columnar regularity which we have just had occasion to admire in Staffa and the Causeway. The castles of Dumbarton, Edinburgh, and Stirling are built upon such masses. At other times it forms low, rugged, and unpicturesque strata, sometimes remarkably bent, but without forming decided columns.

We have already noticed the effects of these rocks upon their neighbours, and upon the strata which they penetrate and invade. As these involve a variety of important theoretical considerations, it will be proper to consider them a little more in detail.

In describing the effects of the intrusion of granite into the superincumbent slates and stratified rocks, we noticed the fragments that occasionally occur in the granitic veins, their induration, and other symptoms of fusion and violence; and in the veins and dykes of basalt we meet with precisely similar effects. Near Edinburgh the sandstone is hardened and rendered like jasper by the whin dykes, and loose pieces are occasionally seen to have been floating as it were in the fused basalt. In Antrim the limestone is sometimes overtopped by basalt, and the dykes as they traverse it harden it into a species of marble, and the neighbouring flints are reddened. In coal mines those accumulations of carburetted hydrogen gas which form what are called the blowers, appear to have resulted from the action of veins of basalt.

In addition to this evidence, we have some of a chemical nature, which is not less decisive; and it is to be regretted that such experiments have not been extended.

The first great experiment of this kind was made by Mr. Gregory Watt; he fused 7 cwt. of fine-grained basalt, and suffered the fused mass to cool gradually, so that the whole process lasted eight days. The mass after fusion was three feet and a half long, two feet and a half wide, eighteen inches thick at one end, and only four at the other. The structure was singularly altered, and in many places there were aggregations of spheroids of a radiated texture, not unlike the globular structure exhibited by some kinds of decomposing basalt, and occasionally forming by their mutual pressure a tendency to prismatic or columnar arrangement.

In glass which has been slowly cooled we occasionally observe somewhat similar and highly interesting effects; its texture is variously modified, and globules of a radiated and crystalline texture are formed in it from a new arrangement of its molecules. And, lastly, certain sandstones and clays may assume in some instances a columnar texture by the action of long-continued heat short of fusion. Dr. M'Culloch observed in a hearthstone of an old furnace which had been in constant work for 18 years, that a prismatic structure extended through its whole mass, and he thus explains the occasional columnar structure of sandstone when in contact of basalt; and in regard to some kinds of basalt itself, he observes that its frequent amygdaloidal structure proves that it was originally cellular and porous like lava, the cells having been subsequently filled up by the infiltration of the various substances found in them. It is a mere dispute about terms, therefore, to refuse to these ancient eruptions the name of *submarine volcanos;* for such they are in every essential point, though they no longer eject fire and smoke.

The examination of the igneous rocks of Sicily has proved that all the ordinary varieties of trap have been produced under the waters of the sea, since the Mediterranean has been inhabited by a great proportion of the existing testaceous species. "We are therefore entitled to feel the utmost confidence that if we could obtain access to the existing bed of the ocean, and explore the igneous rocks poured out within the last 5000 years beneath the pressure of a sea of considerable depth, we should behold formations of modern date scarcely distinguishable from the most ancient trap rocks of our island. We cannot, however, expect the identity to be perfect, for *time* is ever working some alteration in the composition of these mineral masses; as, for example, by converting porous lava into amygdaloids."

§ III.

We have now examined the structure of the crust of our globe, and found it to consist of a succession of sedimentary deposits of different dates, characterized by peculiarities of mineral structure and composition, and by distinct organic relics, upheaved and displaced by a series of crystalline rocks apparently of igneous origin, and in many instances similar in composition and effects to the products of existent volcanos.

These must be now more particularly examined, for the purpose of ascertaining how far we are justified in attributing to analogous agents those stupendous powers of elevation and dislocation which the theory of the crystalline or hypogene rocks has obliged us to call to our aid. The extent of volcanic fires, their connection with earthquakes, the nature of their products, their usual effects, and their modified action under the influence of pressure, are the principal points now requiring attention.

The geographical extent of volcanic districts is very considerable, and demonstrates the universality of subterranean fire in all quarters of the globe. It is true that the points of eruption and the movements of great earthquakes are confined to certain regions in which the volcanic vents are distributed at intervals, and most commonly in a linear direction; but there is abundant evidence that the igneous powers are at work continuously throughout the intermediate spaces, for the ground is from time to time convulsed, gases and vapours are disengaged, and hot springs issue, the waters of which are very commonly impregnated with the same mineral matters which are discharged by the eruption of the volcano.

There are also abundant proofs of the existence of volcanic fires under various parts of the bed of the ocean, where their effects, though at present unseen and unknown, are probably destined to become evident at some future but very remote period.

The substances thrown out by volcanos are chiefly earthy and alkaline bodies in a state of fusion: masses of red-hot and melted rock, stones, cinders, ashes, steam, and various gases are their accompaniments; and although they differ very materially in the quantity of ejected matter, their products so generally agree in quality that they are doubtless all referable to the operations of one cause. What that cause is, is a question which has long been agitated, but is as yet not very satisfactorily determined; although considerable advances have been made towards an explanation of the phenomena by those great discoveries in chemistry which bear the stamp of Davy's name, and which have taught us the existence of a class of bodies possessed of previously unknown and unsuspected properties, and which are in some respects applicable to the solution of the problem before us.

These bodies are the metallic bases of the alkalies and earths; many of which, the moment that they touch water, explode, burn, melt, and become converted into red-hot matter, not unlike some sorts of lava.

It has been said that if we adopt the existence of great masses of these highly inflammable and active metals deep within the earth as one of the causes of volcanic force, that they would remain inactive without water; consequently that the access of water is a necessary condition. We find, in fact, that many of the great volcanos of the world are not far from the sea or from lakes; but it must also be admitted that there are great volcanic districts to which water has no apparent access. In central Asia there is a volcanic district, with an area of nearly 3000 geographical miles, between 300 and 400 leagues distant from the sea. The central chain of the Andes too is at a great distance from the sea, and yet has several active volcanic vents. But we know too little of the interior of our globe, of what hidden waters it may contain, or what may be the subterranean communications of the ocean, to justify us in excluding this theory upon such grounds, were it otherwise satisfactory and accordant.

When these highly inflammable metals act upon water, they combine with its oxygen, and the hydrogen is evolved; and as hydrogen is very rarely traced as a product of volcanic eruptions, its absence has been urged as fatal to this theory. But upon this point we are also not well informed; the hydrogen may be evolved, and yet its presence not determinable; or, if evolved at a high temperature and in the contact of air, it would burn probably with explosion, and reproduce water. Now aqueous va-

pour is often ejected with explosive force from volcanos; and this sudden generation of steam, in part perhaps resulting from the explosive union of hydrogen and oxygen, may be one great source of their power and violence, and of the concussions attendant on earthquakes.

But there are properties of these singular metals which are less evident, and may yet play an active part where their mutual affinities are concerned. In certain proportions, sodium and potassium form an alloy liquid as water, highly inflammable; and when touched by certain other metals, mercury for instance, becoming red-hot and explosive. Now these properties, curious as they are, may possibly belong, in a yet more eminent degree, to certain alloys and other compounds of the metallic bases of the earths, for we know as yet little of the chemical properties of these bodies; and it may be presumed, upon strict analogy, that there may be other agents of a similar kind, and gifted, perhaps, with yet more energetic powers: for who could even have ventured to imagine the existence of such remarkable bodies as potassium and sodium before their discovery? So that upon the whole, if we cannot frame a perfect theory of volcanos upon these chemical principles, they at all events go some way towards an explanation of some of their concomitant phænomena, as will appear from the details we are about to enter upon. One difficulty, however, we are certainly not prepared to meet; namely, the perpetuity, as it may almost be called, of some active volcanos, — volcanos which have continued to burn and throw out lava and cinders, not only for years, but for successive ages. The lava in the crater of Stromboli has been in a state of ignition for 2000 years; so that there must here be a constant accession of heat, if not renovation of fuel.

We have ample evidence of the connection of earthquakes with volcanos; and all great eruptions have commonly been preceded by violent convulsions which have ceased upon the bursting forth of the volcanic fires, as if the pent-up matters had found a vent. All this shows the *cause* of the eruption to be deep below the surface, and perhaps sanctions the notion of the existence of great masses of ignited matter below the rocks that form our mountains; or even the idea of some of the ancient as well as modern geologists, that the interior and nucleus of the globe is in a state of most intense incandescence, — an idea already alluded to when noticing the evidences of change of climate deduced from the examination of fossil plants. Another fact in reference to this view deserves notice; namely, that there is a very manifest connection between volcanic vents situated at great distances from each other. Such a connection has been suspected between Vesuvius and Etna; and some of the volcanos of the Andes appear to alternate in their eruptions, though at great distances from each other.

When lava is examined as near as possible to the vent whence it issues, it is usually a semifluid mass about the consistence of honey. It soon cools externally, and its surface becomes rough and irregular; but, being a very bad conductor of heat, the interior remains red-hot long after the surface has cooled. It is probable that large masses of lava ejected into the sea retain their high temperatures in the central parts of the mass for a great and even indefinite length of time.

The *quantity of matter* which has been thrown to the surface by volcanic agencies during the historical period is very enormous, and may serve to give an idea of their influence in modifying the surface of the globe, when such powers are considered in reference to great periods of time. In illustration of this point we may select the volcanos of Iceland, because our details respecting them are well authenticated; though it must be recollected that they probably fall into insignificance when compared with what has happened in some of those districts of Asia and South America which are ravaged by subterranean fires. In the following sketch of these volcanic districts we shall avail ourselves as hitherto of Mr. Lyell's excellent abstract of volcanic history, as given in his *Principles of Geology*.

Iceland itself is little else than a mass of lava; and so intense is the energy of volcanic action in that region, that some eruptions of Hecla have lasted six years without ceasing. Earthquakes have often shaken the whole island, causing a complete revolution in its geographical physiognomy; such as the rending of mountains, the elevation of some and the sinking down of others, the desertion by rivers of their channels, and the appearance of new lakes. Upon the coast too, and in great depths of water, new islands have been thrown up, some of which have remained and others disappeared. In this island too, the volcanic vents are often in alternate action, one serving, as it were, for a time as a safety valve to the rest; and when, as is often the case, new cones are thrown up, they generally take a linear direction. In 1783, a new island was thrown up off the coast, consisting of high cliffs; and with such an ejection of pumice, that the ocean was covered to the distance of 150 miles, and ships impeded in their course by the shoals of floating stones. Ere a year had elapsed, however, the sea resumed her ancient domain, the volcanic cliffs had disappeared, and nothing was left but a rocky reef from 5 to 30 fathoms under water. In June, Skaptar-Jokul, 200 miles distant from the new isles, threw out a torrent of lava, which in the first place flowed down into the river Skapta, and completely dried it up; its channel was between high rocks, and was in some places 400 to 600 feet deep and 200 broad. Not only did the lava fill these great defiles up to the brink, but overflowed the adjacent country and filled up a deep lake. There was then a short intermission in the eruption; but in a few days it was resumed, and the newly ejected lava flowed rapidly over the surface of the first, and damming up numerous streams, deluged the neighbouring country with water, and destroyed several villages; — when, after flowing for several days, it was precipitated down a tremendous cataract, and filled the profound cavity which the waterfall had been hollowing out for ages. Afterwards the lava took a new direction, and discharging itself into the bed of another river (the Hyversfliot), occasioned a scene of destruction rivalling the former: the lava accumulated to a great depth, and coming to the plains spread out into broad lakes of fire, some of which were from 12 to 15 miles wide, and 100 feet deep. When the fiery lake which filled the valley of the Skapta had been augmented by new supplies, the lava flowed up the course of the river to the foot of the hills where it rises. This eruption continued two years; and when Mr. Paulson visited it eleven years after (in 1794), the lava was still smoking, and its vents filled with hot water. Although the population of Iceland did not exceed 50,000, twenty villages were destroyed, exclusive of those inundated by water; and all the cattle of the district, and more than 9000 human beings, perished.

We have quoted the narrative of this eruption as giving, upon good authority, some notion of the *extraordinary volume* of melted matter produced. Of the two branches of lava, and they flowed nearly in opposite directions, one was 50 and the other 40 miles in length; the extreme breadth of one branch was from 12 to 15, and of the other about 7 miles. The ordinary height of the currents was about 100 feet; but in deep ravines and defiles they sometimes attained 600 feet. How striking a feature, Mr. Lyell remarks, would these streams form in the geology of England, had they been poured out on the bottom of the sea after the deposition, but before the elevation of our secondary and tertiary rocks! and how easily may we now refer the trap and basaltic rocks to similar causes!

But there are some phenomena connected with volcanic action which seem to be caused by yet more extraordinary agents than those we have adverted to; namely, their *great projectile and explosive force*, — the effects of which are, in some instances, upon so stupendous a scale as to appear utterly incredible, had we not the clearest and most unobjectionable evidence. Let us select one or two illustrative relations, and then see how far we are acquainted with any powers or agents in nature adequate to explain the results.

From the era of the discovery of the New World to the middle of the last century, the great volcanic district of Mexico had remained undisturbed. It is an elevated plateau, between 2000 and 3000 feet above the level of the sea, and bounded by hills of ancient igneous origin. It was occupied by fields of sugar-cane and indigo, and watered by two brooks. In June, 1759, alarming sounds and earthquakes preceded the bursting forth of flame from the ground, and fragments of red-hot rocks were thrown to prodigious heights. A great chasm was formed, from which six volcanic cones were thrown up, the least of which was 300 feet high; and Jorullo, the central volcano, was elevated 1000 feet above the level of the plain. It sent forth streams of basaltic lava, including fragments of granitic rocks, and its eruptions did not cease till 1760. Humboldt visited the country forty years afterwards: there then appeared round the base of the cones, and spreading from them over an extent of four square miles, a convex mass of matter, between 500 and 600 feet high, gradually sloping in all directions towards the plains, and which was still so hot that he lighted a cigar in one of its fissures. It was covered with thousands of little mounds, which emitted *steam and sulphuric acid*. The two small rivers lost themselves below the east extremity of the plain, and reappeared as hot springs at its western limit. Humboldt attributed the convexity of the plain to inflation from below, supposing the ground for the extent of four square miles to have puffed up like a bladder to the elevation of 550 feet in the highest part; but of this there seems no good evidence, except the hollow sound made by the steps of a horse upon the plain, and this might result from any porous material. A subsequent eruption of Jorullo happened in 1819, and it is much to be regretted that no European travellers have since visited the spot. It is known, however, that ashes fell in Guanaxato, 140 miles from Jorullo, in such quantity as to lie 6 inches deep in the street; and the tower of the cathedral was thrown down. Of these forces, thus elevating matter from below, and throwing up extensive plains and lofty mountains, we have numerous other instances; and in

further illustration of their great power may cite the elevation of islands in deep water by submarine volcanos. Those off Iceland have been already noticed. In 1811 a volcano forced its way from beneath the sea off the island of St.Michael, one of the Azores, forming a crater above the water a mile in circumference, and about 300 feet high. In the middle of the 17th century an island was thrown up among the Hebrides, which in a month again disappeared. In July, 1731, a volcano rose in the sea between the island of Pantellaria and the coast of Sicily, forming a crater 240 feet diameter and 20 feet above water. Many shoals are no doubt of volcanic origin.

The Pacific ocean, in equatorial latitudes, seems to be one vast theatre of igneous action; and its innumerable archipelagos, such as the New Hebrides, Friendly Islands, and Georgian Isles, are all volcanic, with active vents here and there interspersed. Of such a formation Owhyhee is a magnificent example. The whole mass, estimated as exposing a surface of 4000 square miles, is composed of lava, the highest peaks of which are between 15,000 and 16,000 feet above the level of the sea. The crater of Kiraue is described by Mr.Ellis as situated in a lofty elevated plain, bounded by a precipice 15 or 16 miles in circumference, apparently sunk from 200 to 400 feet below its original level. The surface of this plain, he says, was uneven, and strewed over with loose stones and rocks; and in the centre of it was the great crater. At the edge of it a sublime and appalling spectacle presented itself,—an immense gulf in the form of a crescent, about 2 miles long and 1 wide, and apparently 800 feet deep, yawned beneath; the bottom was covered with one vast flood of burning matter in a state of terrific ebullition, rolling to and fro its fiery surge and flaming billows: fifty-one conical islands, as it were, forming as many distinct craters, rose round the edge of this burning lake, emitting columns of smoke or pyramids of flame; and several of them vomited from their ignited mouths streams of lava, which rolled in blazing torrents down their black indented sides into the lake below.

We may conclude this part of our subject with a brief notice of one other volcano; namely, that of Tomboroo in the island of Sumbawa, the account of which we owe to the late Sir S. Raffles. It began on the 5th of April, 1815. It appears that a Malay prow, while at sea, on the 11th, was enveloped in utter darkness; and that afterwards passing the Tomboroo mountain, at the distance of 5 miles, the commander observed that the lower part appeared in flames, while the upper portion was concealed in clouds. Upon landing to procure water, he found the ground 3 feet deep in ashes, and several large vessels thrown on shore by the concussions of the sea.

At the commencement of the explosion the commander of the E. I C. cruiser Benares, which was at Macassar, supposed that there was an engagement of pirates somewhere in the neighbourhood, so closely did the reports resemble those of cannon. On the 11th the ship was again shaken, as it was thought, by the discharge of cannon. At 8 a.m. on the 12th, the face of the heavens to the south and west had assumed a dingy aspect, and it became darker than it had been at sunrise. A dusky red appearance gradually spread over the heavens; and by 10 it was so dark that a ship could hardly be seen a mile off. By 11 the whole heaven was obscured, except a small space in the east horizon, whence the wind came. The ashes now fell in showers, and the appearances were most awful and alarming. By noon the light which had lingered in the horizon disappeared, and complete darkness ensued. At half-past 7 the next morning there was a glimmering of light, and objects could just be perceived on deck. When day returned the appearance of the ship was most singular; every part being covered with grey dust, which lay in heaps of a foot deep on many parts of the deck. On the 13th the vessel left Macassar, and made Sumbawa on the 18th. Approaching the coast, she encountered an immense quantity of pumice, with numerous burnt trees and logs; and the anchorage was greatly altered, for the vessel grounded on a bank where there had previously been 6 fathoms water. The shores were entirely covered with ashes and cinders ejected from Tomboroo, although 40 miles distant. The explosions were terrific; and there is evidence of their having been heard in Sumatra, upwards of 900 nautical miles from Sumbawa. Lieut. Phillips, who was despatched to afford relief to the perishing inhabitants, learned from the Rajah of Saugar that on the 10th of April the fire and flame raged with exhaustless fury, till all became dark from the quantity of falling matter. At this time stones fell very thick, from the size of a walnut up to that of two fists. Then a whirlwind arose, which destroyed every house in the village of Saugar, tore up the trees, and carried them into the air, together with men and cattle. The sea rose 12 feet above its usual levels, and swept away all within its reach, including some thousands of the inhabitants.

Extraordinary and appalling as these narrations are, they might be greatly extended. In 1772 the inhabitants of a district of Java were alarmed by flashes of light issuing from one of their volcanos. They took flight; but before they could all escape the mountain fell in, with thundering reports like cannon. The extent of ground swallowed up was 15 miles by 6. Forty villages were ingulfed, and 3000 persons destroyed. We have not space to advert to the historical details of Vesuvius and Etna. In the Bay of Naples, Monte Nuovo was thrown up in one day,—nearly 500 feet high, and a mile and a half in circumference. Of the eruptions of Vesuvius there are numerous and excellent narratives. It deserves especial notice in relation to this mountain, that before the Christian era, and from the remotest periods of which we have any tradition, this volcano was in a state of inactivity; affording no other indications of its volcanic character than such as were deducible from the resemblance in its structure to other volcanos, like the *extinct volcanos*, as they are called, of the present day. Pliny does not include it in his list of active vents, but Strabo adverts to its volcanic aspect. Its form was then very different from that which it now exhibits, and the sides were covered with fertile fields; and at its base were the populous cities of Herculaneum and Pompeii. The first symptom of renovated activity was 63 years after Christ, when an earthquake shook the neighbourhood; and in August, 79, it erupted lava. The elder Pliny, who commanded the Roman fleet, then stationed at Misenum, in his anxiety to get a near view of the phenomena was suffocated by the exhalations. His nephew has given a lively description of the scene, but has inexplicably passed over the destruction of Herculaneum and Pompeii. Indeed, so vague are the narratives long subsequent to that event, that had those buried cities never been discovered, the accounts of their tragical end would probably have been regarded as fabulous. Tacitus, the friend and contemporary of Pliny, merely says that cities were destroyed; Suetonius is silent respecting them; Martial adverts to their immersion in cinders; but the first writer who alludes to them by name is Dion Cassius, who flourished about a century and a half after Pliny. We have some interesting historical facts, showing that Pompeii and Herculaneum were destroyed by ashes and mud, and not by red-hot lava. When the amphitheatre at Herculaneum was first cleared out, ashes were arranged on the steps just as snow would lie had it fallen there: the whole superincumbent mass was from 70 to 112 feet deep. The foundation of both cities is ancient lava. It is curious that, notwithstanding the much greater depth of Herculaneum than Pompeii, it was first discovered by the accidental circumstance of a well being sunk in 1713, which came directly down upon the theatre, where the statues of Cleopatra and of Hercules were soon discovered.

In both cities records have been found commemorating their having been rebuilt after they had been thrown down by an earthquake which happened in the reign of Nero, 16 years before the inhumation of the cities. Very few skeletons have been discovered in either city; so that it is probable the greater number of the inhabitants escaped, carrying with them no doubt the principal part of their valuable effects. In the barracks at Pompeii were the skeletons of two soldiers chained to the stocks; and in the vaults of a villa in the suburbs were the skeletons of seventeen persons, who probably fled there for safety: they were found enclosed in indurated tufa, in which was preserved a perfect cast of a woman with an infant in her arms. Although her form was imprinted in the rock, nothing but her bones remained: to these was suspended a chain of gold, and rings with jewels were on the fingers of the skeleton. Earthen amphoræ were ranged along the side of the vault. The writings scribbled by the soldiers in their barracks, and the names of the owners of each house written over the doors, are still legible. The colours of many of the paintings on the stuccoed walls are almost as vivid as if recently painted; and a collection of shells was found in the house of a painter, who probably amused himself with natural history, in as good a state of preservation as if they had remained the same number of years in a museum. The beams of the houses are black exteriorly, but little altered within; and the state of preservation of several animal and vegetable products is truly astonishing. Fishing nets are very abundant; linen with the texture; and almonds, chesnuts, and walnuts in a fruiterer's shop. In a baker's a loaf retaining its form, with a name stamped upon it; and a box of pills upon the counter of an apothecary, with a small cylindrical roll by the side of it, evidently prepared to be cut into pills. In 1827, olives in a square jar, and caviar, were found in a state of wonderful preservation. At Herculaneum the animal and vegetable substances are preserved by having been apparently enveloped in a paste which consolidated, and then allowed them to become slowly carbonized. At Pompeii they are penetrated by a grey pulverulent tufa. The history of the Papyri is well known. It is supposed that only a small part of Herculaneum has as yet been explored, and that the quarters hitherto cleared out at great expense are those where there was the least probability of discovering manuscripts.

It would, however, be irrelevant here to enlarge upon these and other details of buried cities; but the few facts mentioned, and which are abridged from Mr. Lyell's summary, are not without geological importance, as giving some idea of the little change which the lapse of seventeen centuries has effected.

There are many instances of rocks of decided volcanic origin, that is, *extinct* volcanic vents, in districts where all other trace of activity has been lost since the earliest historical times, except hot and mineral springs; such are the Vivarais and Auvergne in central France, and the district of Eifel, near Coblentz, on the Rhine. The attempts to determine the ages of these rocks, or to ascertain the periods of their activity by their association with primitive, secondary, or tertiary strata, are not in general satisfactory: those who are curious upon this point may be referred to the details given by Mr. Lyell.

Important as are the geological results of volcanic action, those of earthquakes, which extend over greater areas, and produce extensive changes in the configuration of the earth's crust, demand perhaps even greater attention.

There can be little doubt as to the unity of cause in volcanos and earthquakes; they frequently precede violent volcanic eruptions, and often seem to arise from explosive matters accumulating their force from want of vent. They are often felt over great extents of territory. The earthquake which destroyed Lisbon, in 1755, was felt over the whole of Europe, and extended even to the West Indies. What enormous powers or forces, therefore, must be called into action in order to produce such extensive results!

It would be useless here to quote long details respecting the effects of earthquakes; but it will be necessary to select two or three illustrative cases, and especially to direct our attention to those phenomena connected with them which immediately bear upon geological changes.

The great earthquake at Lisbon occurred on the 1st of November, 1755. A sound like loud thunder was heard under ground, and instantly afterwards the greater part of the city was shaken down; so that, in six minutes, at least 60,000 persons are said to have perished. The sea first retired, but was violently agitated, and presently rolled in in a huge wave sixty feet high. Many of the largest mountains in Portugal were shaken from their foundations, and most of them were wonderfully split and rent. It was supposed that they emitted fire and smoke; but lightning and dust, perhaps, gave rise to the appearance. The New Quay, a massive marble structure, sunk down with an enormous concourse of persons upon it who had taken refuge there for safety; and it was so ingulfed, that not one of the dead bodies ever floated to the surface; and many vessels anchored near it, and full of people, were swallowed up as in a whirlpool. No fragments of the wrecks ever rose again, and the water upon the spot was deepened by 100 fathoms. Many ships at sea experienced violent concussions. Off St. Lucar, the captain of the Nancy frigate thought he had struck on the ground; but, on heaving the lead, found he was in great depth of water. Another ship, 40 leagues west off St. Vincent, experienced so violent a concussion that the men were thrown up a foot and a half perpendicularly from the deck.

The agitation of the sea during earthquakes has almost always been remarked, and probably such effects are more common than is supposed; for in almost all parts irregularities in its motion are at times observable, which cannot be referred to temporary currents or winds in the offing. The movement is generally a quick flow and reflow of the water, and often so trifling as to escape the attention of all ordinary observers; though detected by seamen and fishermen, who are surprised to find the boats suddenly floated, or as suddenly left dry.

In the Lisbon earthquake, many of the rivers and lakes of Great Britain were singularly disturbed. Loch Lomond suddenly rose between two and three feet, and as suddenly subsided.

In the great Calabrian earthquake, in 1783, an interesting narrative of which is given by Mr. Lyell, the aspect of the country was singularly changed. The earth appears to have had an undulating, vibratory, and horizontal motion; there were the usual tremors in the neighbouring ocean; numerous deep and extensive gaps and fissures were formed, and faults and dislocations in the strata; large landslips took place, and extraordinary lacerations; large buildings and farms were ingulfed; and in some places the chasms closed upon their prey with such violence that on excavating afterwards to recover articles of value, the workmen found detached parts of buildings jammed together in one compact mass. Some of the resulting gaps and ravines were upwards of a mile long, and from 200 to 300 feet deep and broad. Large lakes were formed, sometimes filled with thermal waters from below, and sometimes the consequence of the obstruction of streams; land and houses were in some places uplifted, in others depressed, in others transferred with all their plantations to a distance varying from a few feet to upwards of a mile.

In these narratives it is a matter of much geological importance to establish clearly the fact of elevations and depressions of districts and strata; and, if possible, to ascertain the amount of such change in perpendicular position. Upon these points the Chilian earthquake of 1822 affords some satisfactory evidence. According to Mrs. Graham's (now Lady Calcott's) account, the shock extended for more than a *thousand miles* along the coast, and a great part of the country was bodily elevated for a length of more than a hundred miles; the beach and the bottom near the shore being raised from three to four feet. The uplifting of the former was rendered evident by the adhesion of the shell-fish to the rocks; and it was observed that there were other lines of beach *above that newly elevated, attaining in parallel lines a height of about fifty feet above the sea*, seeming to show that previous elevations had been effected by the same causes. An old wreck of a ship, which before could not be approached, became accessible from the land; cones of earth were thrown up in several districts by the forcing up of water, mud, and sand, through funnel-shaped hollows. The elevation inland appeared, by the effect upon water-courses, to have been two or three times greater than upon the beach.

There are some other points connected with earthquakes and volcanos which, though generally considered of subordinate importance, seem to refer very immediately to their causes; such, for instance, as intermittent and boiling springs, and the escape of carbonic acid gas.

The geysers of Iceland are fine specimens of the former; their waters hold so large a quantity of silica in solution as to incrust every thing they run over. They rise in a tract covered by lava. The Great Geyser springs from a spacious basin at the summit of a mound formed of silicious incrustations deposited by the spray of its waters. In the centre of this basin is a pipe 78 feet deep, through which the water rises, flows over, and is thrown up in jets, attended by loud explosions and subterranean rumblings, and slight tremors of the ground. When these jets are most violent, they shoot to 200 feet high; and after playing for some time, a snorting noise is heard, which gradually becomes as loud as thunder, and steam rushes forth with prodigious violence. This deafening roar lasts for a variable time, and the eruption terminates, coming on again after a variable interval of rest.

Of this phenomenon we have a plausible explanation, and one which bears most importantly upon the theory of volcanos and earthquakes.

Suppose the surface water of the country to penetrate into the chasm A by the fissures B B, while at the same time steam of great force and temperature emanates from the fissures D D. A portion of this steam is first condensed by the water in A, which it gradually raises to its boiling point; then it forms high-pressure steam, and drives the boiling water through the pipe into the basin C, and after the whole has been ejected the steam itself rushes out. Now, if we suppose a number of large subterranean cavities at the depth of several miles below the surface, in which melted lava accumulates, and that water penetrating to these is converted into steam; this, together with other gases pent up, and perhaps liquefied by pressure in similar cavities, or generated by the decomposition of melted rocks, may press upon the lava and force it up the duct of a volcano, in the same manner as the column of water is driven up the pipe of the geyser. But the weight of lava being immense, the pressure exerted on the sides and roofs of such large cavities and fissures may well be supposed to occasion not merely slight tremors, but even violent earthquakes. Sometimes the lateral pressure of the lower extremity of the high column of lava may cause the more yielding strata to give way, and so for a time give relief to the fused matter. Sometimes, on the contrary, a weight equal to that of the vertical column of lava, pressing on every part of the roof, may heave up the superincumbent strata, and force lava into every fissure; which, on consolidation, may support the arch, and cause the land above to be permanently elevated: on the other hand, subsidences may follow the condensation of vapour when cold water descends through fissures, or when heat is lost by the cooling down of the lava.

Besides aqueous vapour, several gases are emitted by volcanos, and among them *carbonic acid*, which is also frequently given out by fissures in the earth, and by mineral springs not associated with direct volcanic action. Its occurrence in the Grotto del Cane is well known. It is given out in enormous quantities near the lake of Laach, and in Brohlthal on the Rhine, where it is used in a chemical manufactory: 600 pounds of the gas are calculated to be discharged from only one of the jets in twenty-four hours. Near Fort Diadine, on the Euphrates, it issues through the cracks of the limestone rocks with a loud hissing noise, and in such quantities as to kill animals that unwarily approach it. The Upas valley, in Java, appears to be a cavity filled to a certain height with carbonic acid: it is about half a mile in circumference, and about 35 feet deep, without vegetation, and covered

with skeletons of men and various animals, such as tigers, hogs, deer, &c., which have perished by their entrance into the gas.

We might enumerate many similar cases of the accumulation of carbonic acid; but those quoted are sufficient to show that it often issues from the strata of the earth in enormous volume, and therefore doubtless from reservoirs where it is pent up under great pressure; and in all probability there are large accumulations of it in a liquid form, in which state it exerts a pressure, at common temperatures, of from 50 to 60 atmospheres upon the walls that confine it, and at higher temperatures of much greater force. We are also perhaps warranted in inferring that there are subterranean cavities, not only filled with this, but probably with other gases, perhaps also in their liquid forms, and of still greater tensive force; and if so, what may not be the mechanical and chemical energies of some of these, acting upon the highly inflammable metals at very elevated temperatures? Upon the whole, it does not appear that powers are wanting adequate to the greatest observed effects; that these are constantly in activity; and that stupendous as the results appear in their collective effects, the great mountains of the globe *may* have been elevated by causes now in action; that, at all events, we *need* not call to our aid unknown powers, since existing causes (especially if it be admitted that they were once more energetic than at present, and that the agents have, as it were, spent a part of their force) appear adequate to the explication of this class of geological phenomena; and if we now have powers in activity, and we have seen that such there are, which are capable of elevating 100 miles of rocky coast 3 or 4 feet, why may not a succession of such elevations, even admitting them not to have been greater than at present, carried on through an indefinite period of time, have occasioned those liftings up of the mountains which we have had such abundant occasion to advert to? It is well known that slight forces continuously repeated produce gigantic effects. It has, says Mr. Lyell, been argued by the opponents of this view, "that it is useless to appeal to time, for time can effect no more than its powers are capable of performing. If, say they, a mouse be harnessed to a large piece of ordnance, it will never move it, even if centuries upon centuries were allowed. This is true enough. But let us suppose a lever applied capable of propelling it forward at the rate of an inch in a century; it is clear that in a sufficient succession of centuries we should have advanced a mile: any force that could move it at all must, if it continue in action, continue to propel it."

The full bearing of this question, however, will be more evident when we have considered the causes which are now effective in producing sedimentary formations, in wearing down the present surface of the globe, and in conjunction with those more violent powers which we have just noticed in giving rise to various superficial inequalities.

§ IV.

We have now surveyed the structure of the earth's surface, and have traced the apparent causes of many of the changes which it has undergone, and which have contributed to its present state and aspect; but there are a variety of processes now active, and of changes now going on, which are slowly tending to modify the existing order of things, and which, if considered in reference to their continuity through past ages, and to their accumulated effects through ages to come, will perhaps assume an air of unexpected importance.

Among the powers of matter which change the earth's surface, heat and cold are obviously at all times concerned in exciting dilatations and contractions, and thus keeping up a perpetual and varying motion among the particles upon which they act. Of such changes the sun is the grand source; to whose varying influence the earth in its diurnal revolutions upon its axis, and in its annual circumvolutions through space, is always exposed.* It may perhaps *seem* that the mere influence of change of temperature, derived from the solar rays, must be of little efficacy in disintegrating hard and solid substances; but when we reflect upon the very extensive range of natural temperatures, and on the great receptive and emissive powers in respect to radiant heat which the surfaces of some rocks present, very considerable transitions from heat to cold, and the reverse, may ensue, and, acting upon certain *textures*, may alone lend powerful aid to that general work of decay which is commonly called the *weathering* of rocks.

But when the influence of change of temperature is conjoined with the varied agencies of water, the powers of destruction will not only be materially increased, but rendered, in many instances, rapid and irresistible. About three fourths of our globe are covered by the waters of the ocean, the mean depth of which is probably about 3 miles. The mean height of the dry land above the ocean's level does not exceed 2 miles; so that the present dry land might be so distributed over the bottom of the ocean that the surface of the globe would present a mass of waters. This is an important possibility, when geologically considered; because, with it at command, every variety of superficial land and water may be imagined, and consequently every variety of organic life, each suited to the various situations and climates under which it would be placed. In consequence of the general uniformity of level preserved by the ocean, it enters the numerous irregularities of the land, and sometimes forms inland seas as it were, in which geological changes, differing from those which occur in the open ocean, may occasionally take place, as in the Mediterranean and the Baltic. There are also inland seas, or *lakes*, as they are usually called, not in direct communication with the open sea; some of salt and others of fresh water. The latter cover very large tracts; and it is obvious that in *them* depositions may take place exclusively characterized by terrestrial and fresh-water remains.

It is also obvious that earthquakes and volcanos will materially contribute towards existing changes, and, cooperating with aqueous forces, may often produce a joint effect to which neither could separately give rise; as when frequent earthquakes aid the excavating power of water in carving out a valley, or widening one which already exists. Of these powers the statements in the preceding section furnish abundant proofs; so that we may now more exclusively attend to aqueous causes, some of which are of a destructive, others of a renovating or reproductive character.

When lands are much elevated above the sea they condense the vapours of the atmosphere, in consequence of their low temperature, and thus become reservoirs of water which irrigate the valleys and plains below, and descending, often by steep declivities, acquire an impetuosity calculated to surmount powerful obstacles. The summits, therefore, of mountains are particularly subject to atmospherical influences, and to great alternations of temperature and moisture. We have already alluded to the gigantic force of water freezing in the chasms and crevices of rocks; and it is in this way that great havoc is effected where comparatively little wet falls, and that the decay of rocks in high latitudes goes on as rapidly, or more so, than where they are deluged by the tropical torrents of rain. This mechanical power of water is often aided by its solvent energies; and although these are usually very slow in their operation, the time for which they are continued and the extent of surface upon which they operate produce a great aggregate effect. Some granitic rocks thus disintegrate apparently by the washing out of their alkaline constituents; in other cases carbonic acid aids the solvent power; and in others the air in water converts black oxide of iron into red, and the decay of the rocks is rapid in proportion to the extent of this conversion. The *granite tors* of Dartmoor and of the Land's End furnish curious instances of the effect of *slow* decay from several causes, among which the tendency in the rock to cubical and prismatic fracture must not be overlooked. By degrees the surfaces become separated; and the wearing continuing to proceed more rapidly near the parts which are most external, and therefore most exposed, the masses which once were angular and prismatic acquire an irregular curvilinear boundary, and the stones assume that appearance which has sometimes been regarded as artificial, and has induced persons to consider them as Druidical remains. Enormous stones are thus thrown from their original positions, and becoming rounder and rounder by the progress of decomposition assume a spheroidal figure, often referred to the continuous action of running water: under favourable circumstances *logging stones* are, as we have previously observed, thus produced. The weathering of some of these tors is so gradual that the life of man scarcely allows an individual to observe a change, whence we may infer the long periods that have been requisite to bring about their present appearances. It is possible that chemical changes may sometimes be aided by the electrical powers called into action, and as a more imme-

* "The sun's rays," says Sir J. Herschel (*Astronomy*, p. 211.), "are the ultimate source of almost every motion which takes place on the surface of the earth. By its heat are produced all winds, and those disturbances in the electric equilibrium of the atmosphere which give rise to the phenomena of terrestrial magnetism. By their vivifying action vegetables are elaborated from inorganic matter, and become in their turn the support of animals and of man, and the sources of those great deposits of dynamical efficiency which are laid up for human use in our coal strata. By them the waters of the sea are made to circulate in vapours through the air, and irrigate the land, producing springs and rivers. By them are produced all disturbances of the chemical equilibrium of the elements of nature, which, by a series of compositions and decompositions, give rise to new products, and originate a transfer of materials. Even the slow degradation of the solid constituents of the surface, in which its chief geological changes consist, and their diffusion among the waters of the ocean, are entirely due to the abrasion of the wind and rain, and the alternate action of the seasons; and when we consider the immense transfer of matter so produced, the increase of pressure over large spaces in the bed of the ocean, and diminution over corresponding portions of the land, we are not at a loss to conceive how the elastic power of subterranean fires, thus repressed on the one hand and relieved on the other, may break forth in points where the resistance is barely adequate to their retention, and thus bring the phenomena of volcanic activity even under the general law of solar influence."

diate agent electricity is not without its influence: The thunder storm shivers rocks and hurls them down in mighty fragments, often fusing their surfaces, and sometimes consolidating soft materials. Near Drig in Cumberland, the sandy soil contains hollow tubes produced by lightning striking and penetrating the ground; some of these have been traced to a depth of 40 feet, and furnish curious illustrations of the passage of the electricity. When running water is mixed with sand and pebbles it acquires a new mechanical power, and these carried along by streams grind down and excavate the adjacent strata, so that the superincumbent portions are ultimately precipitated into the stream. The obstruction causes a temporary accumulation of water behind, which afterwards bursts the barrier; and in this way small ravines are slowly widened into narrow valleys, in which sinuosities are caused by the deflection of the stream first to one side and then to the other. The unequal hardness of the materials through which the channel is eroded tends also to modify the lateral power of excavation, and thus the little stream acquires a serpentine direction. When the flexures are great, a direct line is often restored by the river cutting through the isthmus which separates two or more of its curves. These windings occur from similar causes in some of the largest rivers of the world; and not only in those which flow through flat alluvial plains, but large valleys are excavated to a great depth through solid rocks in this serpentine form. These tortuous flexures of rivers show that the valleys in which they flow were not produced or excavated by any flood of uncommon power and magnitude, or by any diluvial operation; for such causes would probably have produced straight channels.

In referring to the transporting powers of water, it has been justly observed by Mr. Lyell, that we are often surprised at the facility with which small streams bear along sand and gravel; for we usually estimate the weight of rocks in air, and do not sufficiently reflect on their comparative buoyancy when submerged in a denser fluid. The specific gravity of most rocks is only from twice to thrice that of water; so that the fragments lose from a third to half of what we usually call their *weight*.

The power of rivers in transporting mud, sand, and gravel, is shown by the accumulation of those substances at their mouths, where they terminate either in lakes or in the sea; and the history of storms and floods affords many memorable instances of the force with which they transport heavy materials. In August, 1829, Aberdeenshire and the adjacent counties of Scotland were visited by a storm and hurricane which extended over a space of 5000 square miles,—flooding the rivers, carrying away bridges, and removing masses of rock of some tons weight, and transporting from 1000 to 3000 tons of gravel to great distances in one day.

In alpine countries the moving of massive stones is facilitated by the ice which adheres to them, and forms with the rocks a mass of less specific gravity. The glaciers also, formed of consolidated snow, carry down prodigious loads of rock and sand, which are generally ranged in long ridges running parallel to the glacier, and from 20 to 40 feet high. They are slowly protruded into the valleys, where the ice melts, and the whole accumulation is swept away by torrents.

If the materials which streams have to work upon are but loosely consolidated, the rapidity with which they sometimes excavate deep channels is truly astonishing. After the heavy rains which followed the eruption of Vesuvius in 1822, the water flowing from the Atrio del Cavallo cut, in *three days*, a new chasm 25 feet deep.

We may also adduce striking examples of the erosion of deep chasms in comparatively hard and durable materials. Some of the clearest illustrations of this excavating power are presented in the valleys of central France, where the ancient channels of rivers have been filled up by lava, through which the present streams have re-excavated a passage from 20 to 70 feet deep, and often of great width.

This subject has been well illustrated by another case quoted by Mr. Lyell, upon the base of Etna, where a great current of lava descending in 1603 from near the summit of the volcano flowed into the alluvial plain of the Simeto, one of the largest of the Sicilian rivers, which skirts the base of Etna, and falls into the sea a few miles south of Catania. It entirely filled up and obliterated the bed of the river with indurated lava; yet now (that is in the course of two centuries) it has re-excavated for itself a new passage, which is from 40 to 50 feet deep, and more than 100 wide.

But of the numerous examples which might be cited of the powers of rivers to carve out their courses and excavate valleys in their rocky boundaries, the falls of Niagara are perhaps the most magnificent. That river flows from Lake Erie to Lake Ontario, the distance between them being 32 miles; and the level of the former lake is 330 feet above that of the latter. As it leaves Lake Erie, the Niagara is almost level with its banks, and three quarters of a mile wide; so that should it rise 8 or 10 feet, Canada and the state of New York would be inundated. Proceeding towards the falls, it has a descent of 50 feet in half a mile, and rushes with great force. At the verge of the cataract, an island divides it into two falls: one 1800 feet wide, and 158 feet perpendicular; the other 600 feet wide, and 164 feet high. This enormous body of water is precipitated over a ledge of hard limestone in horizontal layers, which rests upon a soft shale. This crumbles away so rapidly, that the harder limestone forms a projecting mass, which overhangs the space below, and being left without support, falls from time to time in large masses into the abyss beneath; occasionally producing shocks which are felt at some distance, and attended by a noise like thunder. As soon as the river has passed the falls, its character is completely changed; it runs furiously in a deep trench cut in the horizontal strata, so that the ravine is only perceived on approaching the edge of the precipice. Through this deep chasm the river flows for 7 miles; and then the table-land, which is nearly level with lake Erie, suddenly sinks down at a town called Queenstown, and the river traverses a plain which continues to the shore of Lake Ontario.

Now it appears probable that the great cataract of the river was once at Queenstown, and has gradually retrograded from that place to its present position, about 7 miles up. Within the last 40 years the falls have receded 50 yards; so that, supposing the ratio of recession never to have exceeded this slow progress, it must have required nearly 10,000 years for the excavation of the whole ravine; and should it not be accelerated in future, it will require nearly 30,000 years for the falls to eat their way backwards to Lake Erie, to which they most undoubtedly seem destined to arrive. Of course this calculation is only provisional, and may be interfered with by many causes; but supposing Lake Erie to remain nearly in its present state, the sudden escape of such an immense body of water would cause a tremendous deluge. But Lake Erie is constantly diminishing in depth by the enormous quantities of matter brought down by the rivers which feed it. Long Point, near the influx of Big Creek River, has advanced three miles within the last three years: another important effect of rivers. There are other causes which in this case would probably prevent a sudden debacle; for the waters of a lake with a rocky barrier can only be suddenly let out so as to produce a deluge when the hard barrier separating it from the land at a lower level presents a perpendicular face to the whole depth of the lake, and accordingly inundations from such causes are comparatively rare. (See *Lyell's Principles*.)

We come now then to consider the further progress of the *detritus* carried down by rivers. It is clear that their tendency will be to fill up valleys and hollows: lakes will gradually diminish in depth, or even be choked up and again cut through; and low lands flooded, and deposits left upon them. In some situations, rivers raise their beds when restrained by artificial embankment. Of this the Po furnishes a remarkable example, traversing the plains upon a high mound like an aqueduct, even more elevated than the roofs of the houses in the city of Ferrara.

In other cases, where two or more streams unite into one river, so that the water does not expose a surface equal to the two previous surfaces, the action of the united waters is to deepen the channel.

Of the matters carried down by rivers large quantities are transported to their mouths, and there deposited either in lakes or in the ocean bed. The Lake of Geneva is thus receiving enormous supplies of detritus from the Rhone; so that from calculations which have been made of its increase, and of the diminution of the depth of the lake, it appears probable that if we could obtain a section of the accumulation formed during the last eight centuries, we should see a great series of strata from 600 to 900 feet thick, and nearly two miles in length, inclined at a slight angle. We should also find a number of smaller deltas at the mouths of the smaller rivers, each composed of such materials as the respective rivers happen to have brought down.

When the Rhone again issues from this lake, it is as pellucid as crystal; but its pure waters are presently again mixed with the turbid sediments of the impetuous Arve, bringing down the granitic detritus of the glaciers of Mont Blanc. It afterwards receives vast contributions from the Alps of Dauphiny, and from the primary and volcanic mountains of central France; and when at length it enters the Mediterranean, it discolours its blue waters with a whitish sediment for the distance of between six and seven miles from its mouth, throughout which space the current of fresh water is perceptible. Mr. Lyell has collected a body of very curious information respecting this and other deltas, of which we can only here hint at the general results.

It appears that by the confluence of the Rhone, and the currents of the Mediterranean driven by winds from the south, sand bars are often formed across the mouths of the river, by which means considerable spaces become divided off from the sea, and subsequently from the river

also when it shifts its channels of efflux. As some of these are subject to the occasional ingress of the river when flooded, and of the sea during storms, they are alternately salt and fresh; so that both fluviatile and marine shells are found in them. Of the new deposits in this delta great part consists of calcareous and arenaceous rock cemented by carbonate of lime. A cannon taken up near the mouth of the river was entirely entombed in solid calcareous rock.

The delta of the Po in the Adriatic presents another instance of the vast accumulations of matter that are thus deposited by rivers; and it appears that within the historical period, that is, within 2000 years, the accessions of land have increased from 2 to 20 miles in breadth. Adria, a sea-port in the time of Augustus, is now about 20 miles inland; and Ravenna, which was also a sea-port, is 4 miles from the main sea.

The delta of the Nile also affords some interesting geological considerations; but we must look to the great rivers of Asia and America for the most instructive examples of these formations.

Of the delta of the Ganges and Barrampooter we have some curious information from Major Rennel. These rivers descend from the highest mountains in the world into a gulf which runs 225 miles into the continent. The part of the delta bordering on the sea is composed of a labyrinth of rivers and creeks, infested by tigers and alligators, and equal in extent to the whole principality of Wales. The mud and sand poured into the gulf in the flood season is so great, that the sea only recovers its transparency at the distance of 60 miles from the coast. And in further proof of the immense transportation of earthy matter, we have the great magnitude of the islands formed in the channels of the river during a period even far short of a man's life. Some of these, many miles in extent, have originated in large sand banks thrown up at points, and afterwards insulated by the stream; others are caused by various accidental obstructions, such as sunk trees or boats. In the great gulf below Luckipoor, some of the islands rival the Isle of Wight in size. These newly-formed lands are soon overrun with reeds, grass, and shrubs, which form impenetrable thickets, where tigers, buffalos, deer, and other wild animals take shelter; so that both animal and vegetable remains must continually be precipitated into the flood, and sometimes become embedded in the sediment of the delta. Crocodiles also swarm upon the shoals; and the habits of these animals are such as to render them particularly liable to become imbedded in the horizontal strata of mud which are annually deposited in the Bay of Bengal over many hundred square miles. Mr Lyell has also gone into the history of the Mississippi, the course of which is very instructive, in consequence of the undisturbed and natural state of its banks, and the varieties of climate through which it flows. Its delta is divided into innumerable lakes, marshes, and streams, inhabited by multitudes of alligators; and millions of logs and trunks of trees are brought down at particular seasons, and either carried out to sea, or bound together by adventitious vegetation, so as to retard the river and become embedded in mud.

We thus find that matters washed down from the decay and disintegration of the land into lakes and seas are there accumulated, and are *now* forming *stratified deposits*, varying in their nature and texture, and often abounding in organic relics; but, to form a just notion of the magnitude of these processes, they must be compared with objects with which we are more familiar. Now it is probable that the waters of the Ganges hold in suspension from 2 to 3 per cent. of solid matter; but if we only assume *one* per cent., which is perhaps the average of most rivers, we are, says Mr. Lyell, brought to the extraordinary conclusion that there passes down, every two days, into the Bay of Bengal, a mass equal in weight and bulk to the great Egyptian pyramid.

We have already adverted to the enormous quantity of matter occasionally ejected by volcanos. The most voluminous current of lava which has flowed from Etna within historical times was that of 1669, calculated at 140 million cubic yards. Now this would only equal in bulk one-seventh of the sedimentary matter carried down in a single year by the Ganges (assuming 1 per cent. of sand); so that allowing seven such eruptions in a century, it would require 100 Etnas to transfer a mass of lava from the subterranean regions to the surface equal to the mud carried down in the same time from the Himalaya mountains into the Bay of Bengal. (*Lyell's Principles of Geology.*)

That enormous quantities of matter, therefore, are thus by slow and silent operations carrying down into the deep, and there forming strata which may one day be upheaved and assume the character of dry land, will now be obvious; and shows how some of the mightiest operations in nature are effected insensibly, without noise or disorder, and without the aid of extraordinary convulsions, mighty deluges, or other temporary and sudden causes. We might form some curious speculations respecting the *nature* of the strata thus forming. Some will be argillaceous, some calcareous, hard and soft, coarse and fine, depending upon a variety of obvious interfering causes: some abounding in organic remains, others without them; and among these, from the number of shipwrecks and other casualties, human remains and works of art must often be abundantly interred.

From the wearing down of rocks and strata, and the excavation of valleys by rivers, streams, and alternations of temperature, we may now take a cursory view of the action of the sea on coasts.

The waves of the ocean operate, in many instances, like mighty artillery, battering and breaking down the solid barriers opposed to their inroads. If the rocks are soft, the wear is proportionately rapid, as we see upon the east coast of our island, where many spots now standing in the sea, or even covered by its waters, are marked in old maps as sites of towns and villages, the inhabitants having gradually retreated inland. Where the rocks are hard, or where they are so stratified as to oppose resistance, the declension of coast is much more gradual. The substances thus delivered into the sea are acted on according to their respective weights, forms, and textures: some transported by tides and currents; others rolled about, and ground down upon the shore; and where indurated masses are contained in softer materials, flints for instance in chalk, they remain at the base of the cliff, and tend to protect it from the breakers and check its further excavation.

Veins and dikes sometimes are curiously exposed and insulated by this wear and tear. Arches are cut out and caverns excavated, and even the hardest rocks often drilled as it were in various directions.

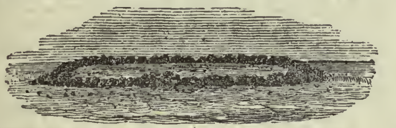
The protecting influence of the waves is seen in those long lines of shingles and sand which often defend low and marshy land, especially at the mouths of valleys, from the access of the sea; and the higher the tide and the heavier the gale, the higher the rampart that is raised. These beaches travel in the direction of the prevalent winds; and of this engineers are practically aware, as we see by the works which they erect to arrest their progress.

An instructive example of the nature and effects of accumulations of this sort is furnished by the Chesil Bank, which connects the Isle of Portland with the mainland; it is about 16 miles long, and the size of the pebbles increases from west to east. Its formation is probably due to a meeting of tides between the peninsula and the land. The storm of 1824 burst over it, and overwhelmed the village of Chesilton. Another example of land thus protected is on the south coast of Devon. What is called Slapton Sands is in fact a ridge of pebbles, which protects and blocks up the mouths of several valleys. Sand is also often accumulated and thrown up in the same way as shingles; and when it is left by the tide and dried by the sun winds often transport it to great distances, so as even to overwhelm large districts, — houses, cultivated lands, and even forests, disappearing beneath them. On the eastern shore of the Bay of Biscay, these moving heaps force lakes of fresh water before them, derived from the rains which are pent up; and several villages in the department of the Landes have been thus buried, and others are now threatened with destruction. They have been calculated to advance at the rate of 60 to 70 feet in a year. Sometimes these sands become consolidated by the percolation of calcareous or ferruginous waters. Of this we have an example on the north coast of Cornwall, where the sand is formed of comminuted shells; and the drift having taken place at different times, the recent sandstone thus formed is stratified with occasionally interposed vegetable remains. Where church-yards have existed, human remains have been entombed; and an old pot of coins has been found in this formation. This rock is so hard that holes are bored in it for the purpose of securing vessels. The parish church of Crantock is built of it. The fossil skeletons of Guadaloupe appear to have been preserved by this species of rock formation.

Among reproductive causes now in action, none are of more curiosity or interest than the operations of the small zoophytic animals which produce coral, and which, labouring on through long periods of time, gradually accumulate such enormous masses of carbonate of lime as to form, together with shells which they entangle and envelope, islands of no inconsiderable dimensions.

Coral reefs are usually of a form approaching to the circular, and the water is shallow in the centre, but surrounded by a very deep, and even unfathomable sea. When the reef is so high as to remain nearly dry at low water, the animals leave off building; and then the rim or edge of the great basin becomes covered by calcareous sand, which offers a foundation for the growth of marine vegetables, and afterwards a resting place for the seeds of trees and plants cast upon it by the waves. Trunks of trees, also carried by rivers from continents and islands, after their long wanderings are often pitched ashore; and sometimes carry with them small animals, such as lizards and insects, which become the first inhabitants. The Pacific ocean, throughout a space comprehended between

the thirteenth parallel of latitude on each side of the equator, is a great nursery of coral islands; also the Arabian and Persian gulfs. Between the coast of Malabar and that of Madagascar there is a great sea of coral. Flinders describes an unbroken reef 350 miles long upon the coast of New Holland; and between that country and New Guinea coral formations extend throughout a distance of 700 miles, interrupted by no intervals exceeding 30 miles in length. The growth of coral is, when compared with human epochs, extremely slow; but the facts just cited show that they have produced results of no mean importance, as influencing the general aspect of the earth's crust. Their circular form, the steep angle at which they plunge into the sea, and the countries in which they occur, render it extremely probable that they are the crests, as it were, of submarine craters; and occasionally lava and volcanic rocks have been found in their central lagoons: these have generally a deep narrow passage, which is kept open by the efflux of the ocean at low tides. These openings are almost always on the



Whitsunday Island in the Pacific, with its enclosed Lagoon.

leeward side, and the windward side of the islands is more complete and perfect than the other; so that, from this fortunate circumstance, ships can enter and sail out with ease; indeed the safety of many of these harbours is entirely dependent upon this cause. It would seem most probably to arise from the large masses of coral rock that are thrown up by the waves on the windward side. These rocks are probably subject to elevations and depressions connected with volcanic agencies. Mr. Lyell thinks that the carbonate of lime, which is the building material employed by the busy little architects of these islands, is in all probability derived from calcareous springs issuing into the sea from fissures in the volcanic bottom.

Section of a Coral Island. — *a a* the habitable part, *b b* the lagoon.

Section of a Coral Island upon a large Scale. — *a b* the habitable part; *b e* slope of the side; *c c* parts of the lagoon; *d d* knolls of coral.

We may now conclude this subject by a brief reference to those erratic blocks and pebbles which are so widely scattered over different districts, and which, with the deposits of bones and stalactite in certain caverns, are often regarded as especial proofs of diluvial action.

Where pebbles occur immediately upon the beach, and are evidently derived from the fragments of neighbouring rocks rolled into form by the action of waves, or where larger masses, forming what are called *boulder stones*, are found in similar situations, or lying upon the strata of which they constitute the fragments and relics, there is no great difficulty in accounting for one or the other; but where immense deposits of gravel are found, not only inland, but out of the reach of all running waters, and where boulder stones are found in similar situations, and very distant from the rocks of which they are the apparent remains, our curiosity and ingenuity are then excited to ascertain how they came into their present places, and whence they are derived. We must of course always carefully distinguish between these importations, as they may be called, of foreign matters, and those kinds of detritus which merely result from the weathering of the rocks.

We have elsewhere pointed out the numerous evidences which we have of fractures, elevations, and depressions of the strata; of the consequent existence of *faults*; and of the formation of valleys, frequently in the line of such faults and fractures. Now it seems clear that all these effects must have been attended in many instances by proportionate changes in the levels of waters, and that there must have been great inundations and torrents passing over such districts at the times of their disturbance; and further, that where land once covered by water has been elevated, rounded masses of rock or boulders, as well as gravel of all degrees of fineness and all manner of composition, may have been elevated along with them. Here, then, are two apparent causes of gravel and boulders.

But independent of these sources of such appearances, there are other geological phenomena, which seem to indicate the passage of great masses of water over the British isles in a direction from north to south: upon the neighbouring continent of Europe, too, evidences of currents setting in the same direction, and transporting gravel and boulders, are not wanting. Of course these currents have in many places been greatly modified as to direction by the valleys, hills, and mountains which they encountered; so that their detritus is in many instances scattered in other directions. In some cases ice, in the form of glaciers, appears to have been a cause of the transportation of masses and fragments of rock to places far remote from their original source. The glaciers which descend from alpine regions are charged with blocks and fragments, and any current of water rushing through the valleys into which they descend would float them and their burthens. It is probable that those immense masses of ice called icebergs are portions of polar glaciers; and these, with their contents, are often floated into warmer climates, so that the debris which they carried with them may thus have been dispersed at the bottom of parts of the ocean far distant from the source of such materials. These circumstances show (when taken in conjunction with the facts already enumerated respecting the causes which influence the decay of rocks) how careful we must be in reasoning respecting the age and sources of blocks, gravel, and those remains generally called *diluvial;* and how difficult it is to form any inference respecting their sources and transport, excepting in cases where these are at hand and obvious. Whatever may have been the cause of such passages of torrents over the land, and the evidences of them are quite sufficient, it is obvious that they must have destroyed nearly all such living beings as came in their way, or as frequented those parts of the earth over which they swept. Accordingly the remains of various animals are found in such deposits; and their examination and comparison with living genera and species, and with those more ancient animals before alluded to in the tertiary and secondary strata, is a very curious and interesting subject of inquiry. Dr. Buckland's researches connected with these relics have given them additional interest, especially as connected with certain theoretical points of diluvial geology, and with their assemblage in caverns. In these caverns the bones are usually mixed with mud, stones, and fragments; and circumstances sometimes seem to show that the animals resided in them for a great length of time: they are covered by *stalagmite*, which forms the pavement as it were of the cave, and effectually conceals and preserves the organic remains. The celebrated Kirkdale cavern in Yorkshire, discovered in 1821, contains the remains of the hyæna, tiger, bear, wolf, fox, weasel, elephant, rhinoceros, hippopotamus, horse, ox, deer, hare, rabbit, rat, mouse, raven, pigeon, lark, thrush, and a species of duck. From the mode in which these remains were strewed over the bottom of the cavern when the mud was removed, the great proportion of hyæna's teeth over those of other animals, and the manner in which many of the bones were gnawed and fractured, Dr. Buckland inferred that this cavern was the den of hyænas during a long succession of years; that they brought in, as prey, the animals whose remains are now mixed with their own; and that this state of things was suddenly terminated by an irruption of turbid water into the cave, which buried the whole in mud. In other caves other animals have been found, indicating the same general facts of the existence of animals now no longer known in these latitudes. Where the bones of man or works of art have been found in these caves, there is generally good evidence of their being of a much later date than the remains of quadrupeds; but occasionally the bones of extinct quadrupeds are so mixed with those of existent testacea as to show that they at least were co-existent.

GE'OMANCY. (Gr. *γη, earth*, and *μάντεια, prophecy.*) Divination by points or circles made on the earth. It was termed by old writers "a part of natural magic, the daughter and abbreviation of astrology." Geomancy was among the acts of divination most sedulously cultivated by professors of that science in the 15th and 16th centuries. Nativities were cast, fortunes predicted, and oracular answers obtained to questions, by the inspection of certain combinations of lines and figures representing the conjunctions of the planets, &c. *See* ASTROLOGY.

GEOME'TRICAL. Something relating to geometry. Thus *geometrical construction* is the representation of a proposition, or of an algebraic equation, by means of a diagram formed by geometrical lines; as straight lines, circles, &c.

Geometrical curves, or *geometrical lines*, are those in which the relation between the abscissa and ordinates is expressed by a finite algebraic equation. *See* CURVE.

Geometrical locus is the line traced by a point which varies its position according to some determinate law. For example, if from any number of given points straight lines are to be drawn to meet in another point, under this condition that the sum of their squares shall be equal to a given space, then innumerable points may be found by which the condition will be satisfied, and the *locus* of all those points is the circumference of a given circle. (See *Simson's Loci Plani*, or *Leslie's Geometrical Analysis.*)

Geometrical progression is a progression in which all

the successive terms have the same ratio. Thus the progressions

$$1, 2, 4, 8, 16, 32, 64, \&c.$$
$$a, a^2, a^3, a^4, a^5, a^6, a^7, \&c.$$

are geometrical; the common ratio of the first being 2, and of the second a. The general property of a geometrical progression is, that the product of any two terms, or the square of any one single term, is equal to the product of every other two terms taken at an equal distance before and after the former. *See* PROGRESSION.

Geometrical Proportion. — Four quantities are said to be in geometrical proportion, or simply proportionals, when the ratio of the first to the second is equal to the ratio of the third to the fourth. Thus, if $a : b$ is equal to $c : d$; then the four quantities, a, b, c, d, are in geometrical proportion. A general property of this proportion is, that the product of the two extreme terms is equal to the product of the two means. *See* PROPORTION.

GEO'METRY. (Gr. γη, *earth*, and μετρον, *measure*.) The science which treats of the properties of figured space. The etymology of the term suggests the object to which geometry was first applied, viz. the measurement of land. It is pretended that the science was invented in Egypt, where the annual overflowing of the waters of the Nile obliterated the land marks, and rendered it necessary to have recourse to measurement in order to ascertain the proper allotment of each individual; but whatever may have been the origin of the *term*, the occasions on which it is necessary to compare things with one another in respect of their forms and magnitudes are so numerous in every stage of society, that a geometry more or less perfect must have existed since the first dawn of civilization.

Objects of Geometry. — In geometry bodies are considered only in reference to the properties of extension or magnitude, figure, and divisibility. Every body occupies in indefinite space a certain determinate place, or finite portion of space, which is called its *volume*. The limits or boundaries which distinguish the place of the body, and separate it from the surrounding space, are called *surfaces*; a surface is therefore common to the two portions of space which it separates. As the limitation of space gives rise to the idea of surface, so the limitation of surface produces *lines*, a line being the boundary of a surface, or the place in which two surfaces intersect each other, and therefore common to both. In like manner the limitation of a line, or the intersection of two lines, produces a *point*. But a point marks only position, and has no properties. A line has length; a surface length and breadth; and a volume length, breadth, and thickness. Hence the properties of lines, the properties of surfaces, and the properties of volumes or solids, comprehend the objects of geometry.

Although the notion of a point is acquired from the consideration of lines, that of a line from the consideration of surfaces, and that of a surface from the consideration of bodies or material objects, it does not follow from this that points, lines, and surfaces are themselves really material. Geometry regards all bodies in a state of abstraction very different from that in which they actually exist; and the truths which it discovers and demonstrates are pure abstractions, — hypothetical truths, which are not, however, on that account, the less useful. For example, it is impossible by any mechanical means to draw a line absolutely straight, or to describe a perfect circle; but the nearer the line approaches to perfect straightness, and the more accurately the circle is described, the nearer will their properties approach to those of the ideal straight lines and circles which are the objects of geometrical consideration. The theorems of geometry are therefore not strictly true in their application to material bodies, but they approximate sufficiently to truth for all practical purposes. They enable us to ascertain, with all the precision of which our senses are capable, the distances of inaccessible objects, the dimensions of a given surface, the contents of a given solid; to compute the distances and motions of the planets; to predict the celestial phenomena; and to navigate a ship from any given point of the globe to any other.

Divisions of Geometry. — Geometry is divided into elementary and transcendental. *Elementary geometry* treats only of the straight line and circle; of figures bounded by straight lines and circles; and of solids bounded by these figures. The circle is the only curve line introduced into the elements of geometry; the simplicity of its description, the ease with which many of its most useful properties are deduced, and the necessity of making use of it in the simplest constructions,— such as raising a perpendicular, measuring an angle, and even making one straight line equal to another, — being reasons for this preference. The construction of algebraic equations of the second degree, and in general all problems that can be solved by means of straight lines and circles, are also referred to elementary geometry. *Transcendental geometry*, properly speaking, is that which has for its object all curves different from the circle; as the conic sections, and curves of the third and higher orders. It comprehends, also, the construction of equations of the third and fourth as well as of the higher degrees. But some writers understand by *transcendental geometry* the applications of the differential and integral calculus to the investigation of the properties of curve lines and surfaces. Geometry is also divided into *ancient* and *modern*; ancient geometry being that form of demonstration and investigation which was employed by the Greeks, and of which *Euclid's Elements* form a well-known example; modern geometry that in which algebra, or the differential or integral calculus, is made use of. We also speak of *pure geometry*, *practical geometry*, and *applied geometry*. *Descriptive geometry* has already been considered under that term.

Methods of Demonstration.—Of the different methods of demonstration adopted in elementary geometry, one of the simplest, and at the same time one of the most fertile, is the method of *superposition*. This consists in showing that two figures being applied to each other, or being laid the one upon the other, entirely coincide, or fill the same space; from which coincidence we infer the equality of all their parts, each to each. Thus Euclid, in order to prove that two triangles which have two sides of the one equal to two sides of the other each to each, and also the angles contained by those sides equal, are equal in all respects, supposes the one triangle to be placed upon the other, and shows that from the hypothesis an entire coincidence must necessarily take place; whence it follows that the remaining angles of the one triangle are equal to those of the other each to each, and the remaining side of the one to the remaining side of the other. On this principle is founded the whole doctrine of the comparison of triangles, and, consequently, of all rectilineal figures; for it is demonstrable that any two equal rectilineal figures may, by resolving them into parts, be applied by superposition one upon the other, so as entirely to coincide.

Another frequently convenient method of demonstration is that which is called by logicians the *reductio ad absurdum*. It consists in assuming the proposition which is announced to be not true, and in reasoning from this assumption till consequences are deduced which are either contradictory of the hypothesis, or of some proposition previously demonstrated. Many examples of this method occur in the *Elements* of Euclid; but it is to be remarked, that though the proof which it gives is perfectly rigorous and satisfactory, the procedure is in some respects indirect, and therefore should not be adopted unless when it affords a shorter and simpler demonstration than can be obtained by a direct mode of reasoning. It is especially applicable to those propositions which are the reciprocals of others already demonstrated, and to incommensurable quantities.

In their more difficult researches, and particularly in those relative to curve lines and surfaces, the ancient geometers had recourse to the *method of exhaustions*. Admitting no demonstrations but such as are perfectly rigorous, they did not consider it consistent with the strictness of geometrical reasoning to regard curve lines as polygons of a very great number of sides; but when they proposed to investigate the properties of any curve, they regarded it as the fixed term to which the inscribed and circumscribed polygons continually approach in increasing the number of their sides. The continual approximation of these polygons to the curve afforded an idea of the properties of the latter, the more accurate as the number of sides was greater. But it still remained to prove, by some recognized principle of demonstration, the truth of the properties that had thus in a manner been divined; and this was done by showing that every supposition contrary to them necessarily led to a contradiction. In this manner they demonstrated that the areas of different circles are to each other as the squares of their respective diameters; the volumes of spheres as the cubes of their diameters; that pyramids of the same height are as their bases, &c. (Carnot, *Réflexions sur la Métaphysique du Calcul Infinitésimal.*)

Analysis and Synthesis.—The Greek geometers employed two distinct modes of investigation, *analysis* and *synthesis*; the one, as the names imply, being the inverse of the other. In the *Mathematical Collections* of Pappus, book vii., analysis and synthesis are thus described: — Analysis is the method which, setting out from the thing demanded, arrives by means of certain established consequences to something known before, or placed among the number of principles acknowledged as true. It passes from a proposition through all its antecedents; and is therefore called *analysis*, or *resolution*, or an *inverted solution*. In *synthesis*, on the contrary, we begin from the proposition with which the analysis concluded, ordering properly the above antecedents, which now present themselves in the form of consequents, and pass from one to another till we arrive at the conclusion sought, or that from which we started in the case of analysis. These two methods have each their peculair use. The first is the method of invention, and is employed in

order to discover a construction which will satisfy the proposed conditions; the second is the method of demonstration, and employed to prove the sufficiency of the construction to which the analysis has led. In general, both methods are employed simultaneously when the object is to discover new relations, or the solution of new problems; but when the object of the geometer is to prove to others the propositions which he has discovered, the synthetical method is usually preferred.

Application of Algebra to Geometry.— A different kind of analysis from that of which we have now been speaking consists in the application of algebra to the solution of geometrical problems. This has opened up a new and rich field, entirely unknown to the ancients, and been the direct cause of the great extension of the modern mathematics. In general, when a problem is of a certain degree of difficulty, the use of the algebraic notation, which substitutes the simple arithmetical operations of multiplication and division for the complex geometrical methods of the composition and resolution of ratios, is attended with great advantage. By the aid of algebra, the properties of curve lines, their tangents, points of inflexion, asymptotes, branches, rectification and quadrature — subjects which the ancient geometry could reach only in some limited cases, and with great difficulty — are demonstrated with the utmost facility. Some mathematicians of eminent rank, delighted with the beautiful specimens of investigation afforded by the ancient geometry, have regretted the extensive application of algebra which characterizes the scientific works of the present day; but in a science which presents so many real difficulties, and in which so many discoveries remain to be made, the path which leads most directly to the object aimed at, and which, moreover, is the easiest to follow, is that which ought to be preferred. Without the aid of algebra and the new calculus, geometry could not have been applied to dynamics, and only in a few limited cases to any other branch of natural philosophy.

History of Geometry.— It has already been mentioned that geometry is supposed to have had its origin in Egypt. From that country it is said to have been transported into Greece by Thales. The celebrated proposition of the square of the hypothenuse was the discovery of Pythagoras. Anaxagoras of Clazomene composed a treatise on the quadrature of the circle; and Plato had certainly made considerable advances in the science, as is proved by the simple and elegant solution which he gave of the duplication of the cube. About fifty years after the time of Plato, Euclid collected the propositions which had been discovered by his predecessors, and formed of them his famous *Elements;* a work which continues to the present day to be regarded as one of the best (if not the very best) introductions to the mathematical sciences. It consists of fifteen Books, of which thirteen are known to have been written by Euclid; but the 14th and 15th are supposed to have been added by Hypsicles of Alexandria. Apollonius of Perga, about 250 years B.C., composed a treatise on the *conic sections*, in eight books; and he is said to have been the first who applied to those curves the appellations by which they have ever since been distinguished,— namely, the parabola, the ellipse, and the hyperbola. (*See* CONIC SECTIONS.) About the same time flourished Archimedes, the most illustrious of the ancient philosophers, who distinguished himself in geometry by the discovery of the beautiful relations between the sphere and cylinder, by his work on *conoids* and *spheroids*, by his discovery of the exact quadrature of the parabola and his very ingenious approximation to that of the circle. In the list of names which have come down to our times in connection with geometry, we may mention Eudoxus, Archytas, Eratosthenes, Aristarchus, Dinostratus, and Nicomedes; but for an account of the discoveries or inventions by which they are individually celebrated, we must refer to Montucla's *Histoire des Mathématiques.* The school of Alexandria produced Pappus and Diophantus; but the Greek geometry, though it was afterwards enriched by many new theorems, may be said to have reached its limits in the hands of Archimedes and Apollonius; and a long interval of 17 centuries elapsed before this limit was passed. In 1637, Descartes published his *Geometry;* a work which will ever be remarkable, as containing the first systematic application of algebra to the solution of geometrical propositions. Soon after this followed the discovery of the *infinitesimal calculus;* and from that time to the present geometry has shared in the general progress of all the mathematical sciences.

Works on the Ancient Geometry:— Euclid, *Elements of Geometry*, and *Book of Data;* Apollonius, *Conics;* Archimedes, *Opera;* Pappus, *Mathematicæ Collectiones;* Vieta, *Opera Mathematica;* Huygens, *Opera;* R. Simson, *Opera Reliqua*, and *Loci Plani;* Stewart, *Propositiones Geometricæ;* T. Simpson, *Elements of Geometry;* Legendre, *Elements of Geometry;* Leslie, *Elements of Geometry*, &c. For an account of the numerous editions of *Euclid's Elements* (which have been translated into every European language), see Murhard, *Bibiliotheca Mathematica;* but to the list contained in that work should be added the more recent edition of Peyrard, in Greek, Latin, and French (Paris, 1814). An edition of the first six books, in Greek and Latin, by Camerer and Hauber (Berlin, 1824), also deserves to be noticed, on account of the valuable notes with which it is accompanied.

GEOPO'NICA. (Gr. γη, and πονη, *labour.*) The name of a Greek compilation of precepts on rural economy, extracted from ancient writers. The name of the compiler is unknown; but the authorities which he quotes are numerous, and deservedly celebrated. (See Niclas's edition, 4 vols. 8vo. Leipsic, 1781.)

GEO'RGICS. (Gr. τα γεωργικά, *things pertaining to husbandry.*) The title of a poem of Virgil's, in four books, on agriculture, and the care of cattle, bees, &c. It is considered the most perfect of his works.

GEORGIUM SIDUS. *See* URANUS.

GERA'NIA'CEÆ. (Geranium, one of the genera.) A natural order of herbaceous or shrubby Exogens, growing in most parts of the world, nearly related to *Oxalidaceæ*, *Balsaminaceæ*, and *Tropaolaceæ*, with which they are by some botanists associated. They are distinguished by the peculiar dehiscence of their fruit, the tumid joints of their stem, and their stipulate leaves. Their sensible properties consist in an astringent principle, and an aromatic or resinous flavour. Many of them, especially those of the genus *Pelargonium*, are beautiful objects, and much cultivated in gardens.

GERMAN SCHOOL. In Painting. In this school we find an attention to individual nature, as usually seen, without attempt at selection, or notion of ideal beauty. The German painters seem to have set a particular value on high finishing, rather than on a good arrangement and disposition of the subject. Their colouring is far better than their drawing, but their draperies are generally in bad taste. Though among the painters of this school some are free from the application of these observations, they are not sufficient in number to change the general judgment that must be passed upon it. Wohlgemuth, Holbein, and Albert Durer are the heads of it. These observations do not apply to a school which seems now rising in Germany, and which, with such leaders as Retsch and others, seems likely to put the school of painting there on a level with its highly splendid intellectual powers in all other branches of the arts and sciences.

GE'RMEN. (Lat. *a bud.*) In Botany, the organ commonly called the *ovarium.*

GERMINA'TION. (Lat. germen.) The process by which a plant is produced from a seed. The phænomena of germination are best observed in dicotyledonous seeds; such, for instance, as the bean, pea, lupin, &c. These seeds consist of two lobes or cotyledons, enveloped in a common membrane; when this is removed a small projecting body is seen, which is that part of the *germ* which afterwards becomes the root, and is termed the *radicle:* the other portion of the germ is seen on carefully separating the cotyledons, and is termed the *plumula;* it afterwards forms the stem and leaves. When the ripe seed is removed from the parent plant it gradually dries, and may be kept often for an indefinite period without undergoing any change; but if placed under circumstances favourable to its germination, it soon begins to grow: these requisite circumstances are a due temperature, moisture, and the presence of air. The most favourable temperature is between 60° and 80°; at the freezing point none of the more perfect seeds vegetate; and at temperatures above 100°, the young germ is usually injured. No seed will grow without moisture: water is at first absorbed by the pores of the external covering, and decomposed; the seed gradually swells, its membranes burst, and the germ expands. The root is at first most rapidly developed, the materials for its growth being derived from the cotyledons; and when it shoots out its fibres or rootlets, these absorb nourishment from the soil, and the plumula is developed, rising upwards in a contrary direction to the root, and expanding into stem and leaves. For this growth the presence of air is requisite; if it be carefully excluded, though there be heat and moisture, yet the seed will not vegetate. Hence it is that seeds buried very deep in the earth, or in a stiff clay, remain inert; but, on admission of air by turning up the soil, begin to shoot forth. From experiments which have been made upon the germination of seeds in confined atmospheres, it appears that the oxygen set free by the decomposition of water combines with a portion of the carbon of the seed, and carries it off in the form of carbonic acid, and that the consequence of this is the conversion of part of the albumen and starch of the cotyledons into gum and sugar; so that most seeds, as we see in the conversion of barley into malt, become sweet during germination. Light is injurious to the growth of a seed. It is, therefore, obvious that the different requisites for germination are attained by placing a seed under the surface of the soil warmed by the sun's rays, when it is moistened by its humidity and by occasional showers;

excluded from light, but within reach of the access of air.

When the young plant is perfected, the cotyledons, if not converted into leaves, rot away, and the process of nutrition is carried on by the root and leaves: the principal nourishment is taken up from the soil by the root, and chiefly by its small and extreme fibres; so that when these are injured or torn, as by careless transplantation, the plant or tree generally dies. The matters absorbed, consisting of water holding small portions of saline substances, and of organic matter in solution, become the *sap* of the plant; and this is propelled upwards in the vessels of the stem, or of the outer layer of wood, into the leaves; here it is exposed to the agency of air, or of light: it transpires moisture, and occasionally carbonic acid. But the leaves also at times absorb moisture, and during the influence of light they decompose the carbonic acid, and, retaining the carbon, evolve oxygen; the sap thus becomes modified in its composition, and the characteristic proximate principles of the vegetable are formed. These return in appropriate vessels from the leaves, chiefly to the inner bark, where we accordingly find the accumulation of the peculiar products of the plant: they also enable it annually to form a new layer of wood. Hence it is that the transverse section of the wood exhibits as many distinct zones as the tree is years old. We are ignorant of the causes of this circulation of the sap; but that it does follow the cause which has been stated is proved by the operation which gardeners call *ringing*, and which they sometimes resort to, to make a barren branch bear flowers and fruit: it consists in cutting out and removing a circular ring of bark, so as to prevent the return of the sap by the descending vessels, which at first ooze copiously, but afterwards the wound heals, and the juices are accumulated in all parts above the extirpated ring, producing tumefaction in the limb, and often inducing a crop of flowers and fruit, or causing those to appear earlier than on the uncut branches. If a tree be wounded so as to cut into the central portions of the wood, or the outer layer of new wood, the flow of ascending sap is then seen to take place upon the lower section, where the vessels are that carry it up to the leaves; and the flow of descending is principally confined to the upper section of the inner bark, from which, after a time, new bark is produced, and the parts again united.

GE'ROCO'MIA. (Gr. γερων, *an aged person*, and κομειν, *to be concerned about*.) That part of medicine which relates to the diet and treatment of old age.

GERU'SIA. (Gr. γερουσία, *an assembly of elders*.) In Ancient History, the senate of Sparta. The number of this council was thirty, including the two kings; and the qualifications of its members were, pure Spartan blood, and an age not below sixty years. The election was performed in a primitive manner by acclamation, the candidates being brought forth one by one before the people. He who was greeted with the loudest applause was held to receive the highest honour next the throne. The functions of the gerusia were partly deliberative, partly judicial, and partly executive. It prepared measures which were to be laid before the popular assembly; it exercised a criminal jurisdiction, with power of capital punishment; and also wielded a kind of censorial authority for the correction of abuses. (See *Mem. de l'Acad. des Inscrip.* vol. xv.; *Müller's Dorians*.)

GE'SNERA'CEÆ. (Gesnera, one of the genera.) A natural order of herbaceous Exogens, inhabiting the tropics, allied to *Bignoniaceæ;* from which it differs in the partly inferior one-celled ovary, apterous seeds, and habit; from *Cyrtandraceæ* in the one-celled ovary, simple placenta, and albuminous seeds; from *Scrophulariaceæ* by the same characters, with the exception of the seeds. The fruit, when succulent, is sometimes eatable, mucilaginous, and sweetish. Many beautiful species of *Gloxinia, Gesnera*, and *Sinningia* are known in our gardens.

GEY'SERS. (From an Icelandic word signifying *raging* or *roaring*.) The celebrated spouting fountains of boiling water in Iceland. The Geysers are situated about 30 miles from the volcano Hecla, in plains full of hot springs and steaming fissures. Their jets are intermittent, and the height to which they rise appears to vary much at different times. Olafsen and Povelsen estimate that of the Great Geyser, when they saw it, at 550 feet. Few English travellers have seen it spout higher than 90 or 100; but Mr. Henderson saw it reach 150 feet in 1815, and one of the smaller Geysers, when a stone was thrown into it, 200. The latest account of the Geysers is in the work of the Hon. A. Dillon (*A Visit to Iceland*, 1840).

GHAUTS. A term applied originally to the narrow and difficult passes in the mountains of Central Hindostan, but which has been gradually extended to the mountains themselves. They consist of two great chains extending along the east and west coasts of the Deccan, parallel to each other, or rather diverging, and leaving between them and the sea only a plain of 40 or 50 miles in breadth. The precise altitude of these mountains has not been ascertained, but their general elevation is from 3000 to 4000 feet; and while the extent of the Eastern Ghauts has been limited to a line of 300 miles, the chain of Western Ghauts is said to extend without interruption nearly 1000 miles. See *Murray's Encyc. of Geography*.

GHEBRES. *See* GUEBRES.

GHI'BELLINES. In Italian History, the name of a political party, which maintained the supremacy of the German emperors over the Italian states, and their claims to investiture, &c., disputed by the Popes. *See* GUELFS.

GHOST. *See* DÆMON, DÆMONOLOGY, APPARITION.

GHOST, HOLY, ORDER OF. The principal military order of France under the old regime; instituted in 1574 by Henry III., for nobles only; abolished at the Revolution; reconstituted by the Bourbons.

GIANT. (Gr. γιγας; said to be the same with γηγενης, *earth-born*.) The giants of Grecian antiquity are not the same with the Titans, although frequently confounded with them in poetry: the latter were produced by Earth to combat Saturn; the former afterwards, against Jupiter. (*Servius ad Æn.* ii. 40.) They were destroyed by the gods of Olympus, in the famous giganto-machia, or giant-fight, of which the scene was laid in the Campi Phlegræi of Campania. The appellation "giant" in the Old Testament, given to various races of men, is thought rather to refer to violence, power, &c., than to actual stature; but individual giants, such as Og and Goliath, are undoubtedly recorded. In Northern Mythology, the giants were the aboriginal inhabitants of the earth (*Olaus Magnus*, book v.), called Josnar. There is a learned as well as amusing article on this subject in the *Enc. Metr.* (See for remarks on natural deviations from ordinary stature in individuals and races of men, *Pritchard's History of Mankind*, vol. ii.; Lawrence, *Lectures on Man*.)

GIAOUR. (Turk. *a dog*.) An epithet conferred on all, but more especially on Christian unbelievers, as those who do not profess an adherence to Mohammedanism are styled by the Turks.

GI'BBET, or JIB. The projecting beam of a crane on which the pulley is fixed.

GIBBO'SE. (Lat. gibba, *a hunch*.) Humped. When a surface presents one or more large elevations.

GI'BBOUS. (Lat. gibbus, *convex, protuberant*.) This term is applied in Astronomy to the appearance of the moon when more than half full or enlightened. In the telescope, the planet Venus exhibits a similar appearance.

GIE'SECKITE. A mineral discovered in Iceland by Giesecke. It is a hydrated silicate of alumina and potash: it occurs in brownish hexagonal prisms.

GIFT, in Law, is, in its general sense, a conveyance which passes either lands or goods. But when restricted to immoveable property, it signifies in its proper sense the creation of an estate tail. (*See* FEE-TAIL.) It is so termed from the operative words of the conveyance, which are always "I give," or "have given." A gift of personal property differs from a grant in being wholly gratuitous and without consideration.

GIGA, or JIG. (Ital.) In Music, an air for dancing in triple time, usually $\frac{6}{8}$ or $\frac{12}{8}$.

GIGA'NTOMA'CHIA. (Gr. γιγας, *a giant*, and μαχη, *a battle*.) In Painting, representations of combats with or between giants. The term is more particularly applied to the conflicts waged between Jupiter and the giants. *See* GIANT.

GIG. A well-known kind of light carriage drawn by one horse. *Gigs, or gig machines*, are rotatory cylinders covered with wire-teeth, for teazling woollen cloth.

GI'LDING. The application of a superficial coat of gold on wood, metal, and other materials. The beauty and durability of gold render it the most valuable of all ornamental substances; but, on account of its weight and high price, its use in these respects would be exceedingly limited, were it not the most extensible and divisible form of matter, so that it may be made to cover a larger surface than an equal quantity of any other body. Metals are usually covered with gold by the process of *water gilding*. It consists in perfectly cleaning their surface, and then, in the case of silver, for instance, rubbing it over with a solution of gold in mercury, called *amalgam of gold:* the vessel is then heated over a clear charcoal fire, by which the mercury is driven off, and the gold left adhering to the silver surface, upon which it is afterwards burnished. The surface of copper or brass is usually prepared by cleaning and rubbing it over with a solution of nitrate of mercury, which amalgamates the surface, and enables the gold amalgam, when subsequently applied, to adhere; heating and burnishing are then resorted to as before. Brass and copper buttons are gilt in this way; and the requisite quantity of gold is so small that twelve dozen buttons of one inch diameter may be completely gilt upon both surfaces by five grains of gold. Other kinds of gilding are performed by gold leaf, which, if intended for out-door work, is laid on by the help of *gold size*, which is drying oil mixed with calcined red ochre; or, if for picture and looking-glass frames, they are pre-

pared by a size made by boiling parchment clippings to a stiff jelly, and mixed with fine Paris-plaster or yellow ochre. The leaves of books are gilt upon the edges by brushing them over, while in the binder's press, with a composition of four parts of Arminian bole and one of powdered sugar candy mixed up with white of egg; this coating, when nearly dry, is smoothed by the burnisher, then slightly moistened, and the gold leaf applied and burnished. To impress gilt figures on book covers, the leather is dusted over with finely powdered mastic; the iron tool by which the figure is made is then moderately heated and pressed upon a piece of leaf-gold, which slightly adheres to it; being then immediately applied to the leather with a certain force, the tool makes an impression, and, softening the mastic, transfers and fixes the gold. In gilding glass and porcelain, powdered gold is blended with gum-water and a little borax, and applied by a camel-hair pencil; the article is then put into an oven or furnace; the gum burns off, and the borax, by vitrifying, cements the gold to the surface, upon which it may afterwards be polished by the burnisher. Within the last few years nearly all the gilt articles manufactured at Birmingham, such as buttons, neck-chains, ear-rings, and so forth, have been gilt by a process patented by Mr. Elkington, in which, after the articles have been properly cleansed by a weak acid, they are immersed in a hot solution of nitromuriate of gold, to which a considerable excess of bicarbonate of potash has been added; in the course of a few seconds they thus receive a beautiful and permanent coat of gold.

GI'LLIESIA'CEÆ. (Gilliesia, one of the genera.) A small natural order of Exogens, allied very nearly to *Liliaceæ*, of which they may in fact be considered an anomalous form. Their principal peculiarity consists in having irregular flowers, surrounded externally by calyx-like bracts. They inhabit Chili, are little known, and of no known use.

GILLS. Parts of the body are so called in which the blood-vessels are in greater number than is necessary for mere preservation or growth, and are minutely subdivided for the purpose of submitting the blood to the influence of air contained in water.

GI'MBALS, or GIMBOLS. (Lat. gemellus, *a pair*.) A piece of mechanism consisting of two brass hoops or rings which move within one another, each perpendicularly to its plane, about two axes placed at right angles to each other. A body suspended in this manner, having a free motion in two directions at right angles, will assume the vertical position: hence the apparatus is employed for suspending portable or mountain barometers, sea-compasses, &c.

GI'MLETING THE ANCHOR. Turning it by the stock round its shank as an axis, like a gimlet.

GIMP. Silk twist, interlaced with brass or other wire

GIN. (Fr. genievre, *juniper*.) Ardent spirit flavoured by the essential oil of juniper. It was originally made by the Dutch, and is hence distinguished in this country by the name of Hollands. The liquor bearing the above name in this country is of British manufacture, and is frequently flavoured by oil of turpentine, and rendered biting upon the palate by caustic potash. In Holland, the finest gin bears the name of Schiedam, the principal place of its manufacture, and where there are many distilleries. Owing to the excessive duty, 22*s*. 6*d*. per gallon, gin is one of the principal articles of clandestine importation. *See* Spirits.

Gin, in Mechanics, is a machine used for raising great weights, driving piles, &c. It usually consists of three long legs or spars, which support a pulley at the top, round which a rope is passed for elevating the weight.

GI'NGER. The dried rhizoma of *Zingiber officinalis*, a native of the East Indies, and abundantly cultivated in America and the West India islands, whence Europe is chiefly supplied. It is a good stimulant and carminative; and the fresh root preserved makes an agreeable, warm, and not very unwholesome sweetmeat. The acrimony of ginger appears to reside in a peculiar extractive matter which is soluble in alcohol; hence a spirituous tincture of ginger contains the virtues of the root.

GI'NSENG. A Chinese word applied to the root of the *Panax quinquefolium*: it has a bitter-sweet flavour, and is considered as a powerful restorative in China, where its consumption is very great. It is found chiefly in the northern parts of Asia, and in America; but it is almost wholly from the latter source that the Chinese draw their supplies. In 1832, there were sent from the United States to China 407,067 lbs. of ginseng, valued at 99,303 dollars. (See *Commercial Dict.*)

GIPSY. *See* Gypsy.

GIRA'FFE. (Arab. xariffa.) The tallest quadruped on the face of the earth, and the largest and most singular of the Ruminant order. Pliny informs us that it was called *Nabun* by the Æthiopians of his time, and *Camelopardalis* by the commonalty at Rome. "*Nabun* Æthiopes vocant, collo similem equo, pedibus et cruribus bovi, camelo capite, albis maculis rutilem colorem distinguentibus, unde appellata *camelopardalis*. Dictatoris Cæsaris circensibus ludis primum visa Romæ." (*Hist. Nat.* lib. viii.) The natural philosophers of Rome had again, subsequent to the gorgeous spectacles of Cæsar, the means of studying the living giraffe. Not fewer than ten of these rare and beautiful animals were publicly exhibited at one time by the third *Gordian*, which afterwards were brutally slaughtered in the arena of the amphitheatre, at the millenarian games, in the reign of the emperor Philip. Notwithstanding these opportunities, all the zoological information regarding the giraffe which we derive from the naturalists of Rome is comprised in the brief notice above quoted from the writings of Pliny; a notice which is too vague to have served to enable us again to recognize the strange compound of horse, ox, camel, and pard exhibited to the wondering Romans, had it not been more intelligibly recorded in medals, mosaic pavements, and the ornaments of public buildings. The resemblance of the giraffe to the horse in regard to its neck is restricted to the presence of a mane, composed of short stiff black hairs, which resembles rather that of the gnu or ass. In the length, slenderness, and flexibility of the neck, the giraffe surpasses all other quadrupeds; the comparison of the legs and feet of the giraffe to those of the ox is still less fortunate, because the two posterior or spurious hoofs common to the ox with most other Ruminants are wanting in the giraffe, as in the camel; but the toes are not joined to a common broad elastic sole, as in the camel; they are completely separated, and provided each with a well-formed sharp-pointed hoof. The head of the giraffe resembles that of the camel in the absence of a naked muzzle, and in the shape and organization of the nostrils, which are oblique and narrow apertures, defended by the hair which grows from their margins, and surrounded by cutaneous muscular fibres by which the animal can close them at will. This is a beautiful provision for the defence of the air passages and the irritable membrane lining the olfactory cavities, against the fine particles of sand which the storms of the desert raise in almost suffocating clouds. The large, dark, and lustrous eyes of the giraffe, which beam with a peculiarly mild but fearless expression, are so placed as to take in a wider range of the horizon than is subject to the vision of any other quadruped. While browsing on his favourite acacia the giraffe, by means of his laterally projecting orbits, can direct his sight so as to anticipate a threatened attack in the rear from the stealthy lion, or any other foe of the desert. To an open attack he sometimes makes a successful defence by striking out his powerful and well-armed feet; and the king of beasts is said to be frequently repelled and disabled by the wounds which the giraffe has thus inflicted with his hoofs. The horns of the giraffe, small as they are, and muffled with skin and hair, are by no means the insignificant weapons that they have been supposed to be. We have seen them wielded by the males against each other with fearful and reckless force; and we know that they are the natural arms of the giraffe most dreaded by the keeper of the present living giraffes in the Zoological Gardens, because they are most commonly and suddenly put in use. The giraffe does not butt by depressing and suddenly elevating the head, like the deer, ox, or sheep; but strikes the callous obtuse extremity of the horns against the object of his attack with a sidelong sweep of the neck. One blow thus delivered at full swing against the head of an unlucky attendant would be fatal; — the female once drove her horns in sport through an inch deal board. Notwithstanding those natural arms of hoofs and horns, the giraffe does not turn to do battle except at the last extremity; where escape is possible, it seeks it in flight. This is extremely rapid, especially along rising ground; but cannot be maintained for a sufficient period of time to enable it to escape the Arab mounted on his long-winded steed. The paces of the giraffe, owing to the disproportion between his long legs and short body, are very peculiar; when walking at a brisk rate, it seems to move forward simultaneously the two legs of the same side, as noticed of old by the learned bishop of Sicca, in his account of the presents brought to Hydaspes by the ambassadors of the Axeomitæ (Abyssinians). "It differed," says Heliodorus, "in gait from every other land or water animal, and waddled in a remarkable manner: each leg did not move alternately, but those on the right side moved together independently of the other, and those on the left in the same manner, so that each side was alternately elevated." Both legs of the same side are undoubtedly off the ground at the same time through the greater part of the step; but upon a close inspection the hind-leg is always seen to be first lifted from the ground, and after a very brief interval the fore-leg of the same side is moved. In the sanded paddock appropriated to the giraffes in the Zoological Gardens, they exhibit in the warm days of summer all their various and singular paces. In the simple walk the neck, which is then stretched out in a line with the back, gives them a stiff and awkward appearance; but this is entirely lost when they commence their graceful undulating canter. To judge by the movement of the legs, this pace appears to be less rapid than it

actually proves, when the extent of ground is observed over which it has carried them in a given time. The motions of the legs are now very peculiar and uncommon; the hind pair are lifted alternately with the fore, and are carried, or rather swung forward, outside of and beyond them at each bound. When excited to a swifter pace they often kick out their hind-legs during their course, and their nostrils are then actively and unwontedly dilated. The general figure of the giraffe, its raised anterior parts, elongated neck, light and tapering head, and long, slender, and flexible tongue, are all conditions which beautifully harmonize with its geographical position and the nature of its food. No Ruminant of its magnitude could exist in the arid tropical regions to which the giraffe is peculiar, if it were not modified so as to be able to obtain vegetable sustenance independently of ordinary pasturage. But in those localities shrubs and trees continue to put forth buds and leaves when all the herbage on the surface of the earth is scorched up; and it is for the purpose of browsing on the green food supplied by lofty branches that the Ruminant type is modified in so extraordinary a manner as we witness it in the giraffe. A zoologist, ignorant of the giraffe, could never have anticipated or conceived so beautiful and perfect a solution of this difficult problem in the scheme of animal enjoyment. The tongue is an organ exquisitely formed for prehension; it is used to hook down the branches which grow beyond the reach of the muzzle of the giraffe, and the animal in captivity instinctively puts it to use in a variety of ways. We have seen the giraffe, in the Jardin des Plantes at Paris, stretching upwards its neck and head, and protruding its tongue to the full extent to hook out single straws, which were platted into the partition separating it from the contiguous inclosure. In our own menagerie at Regent's Park many a fair lady has been robbed of the artificial flowers which adorned her bonnet by the nimble filching tongue of the rare object of her admiration. The giraffe seems, indeed, to be guided more by the eye than the nose in the selection of objects of food; and if we may judge of the apparent satisfaction with which the mock leaves and flowers so obtained are masticated, the tongue would seem by no means to enjoy the sensitive in the same degree as the motive powers. The difference in the size of the nerves of sensation and motion which we observed in the dissection of the tongue accords with these habits of the living animal. From the same dissection it was proved that the movements of the tongue, both those of extension, prehension, and retraction, were due to muscular, and not, as Sir Everard Home supposed, to vascular action. Observations of the living animal, and dissection of the dead, have at length dispelled most of the errors and doubts which obscured the exact knowledge of the nature and zoological affinities of the giraffe. Up to a very recent period we find it described as having callosities on the knees and over the sternum, like the camel, and as a kind of lusus with three horns; of which one, being articulated over a suture in the middle line of the forehead, seemed to take away from the chimerical nature of the unicorn by indicating a transition to that heraldic monster. The truth is, however, that the giraffe possesses neither those callosities nor this median articulated horn. It is essentially a true Ruminant, having a stomach divided into four compartments, the paunch being simply papillose, without water bags; and the reticulum with extremely shallow hexagonal cells, as in the reindeer. It is also a horned Ruminant, the horns being two in number, small, straight, and simple, like those of the pricket deer. But in the giraffe the bony base of each horn is articulated by a broad rough epiphysial basis to the cranium; it is covered by a vascular periosteum and a hairy integument, which is not deciduous. These horns, or rather antlers, terminate in a truncate extremity capped with a callous plate, and fringed with long and strong black hairs: these horns are present in both sexes, as in the reindeer; and are larger in the male. The median protuberance is a simple thickening of the contiguous parts of the frontal and nasal bones. In the form of the mouth the giraffe differs from every other Ruminant. The upper lip is not bifid, as in the camel; and though it is prolonged and covered with hair, as in the elk, it differs in its elegant and tapering form.

The giraffe has a long neck, and has not spurious hoofs, and this far it resembles the camel; but the cervical vertebræ in the camel tribe present a peculiarity of structure, combined with their length, in which the giraffe does not participate. The camels have many other peculiarities of internal organization, to some of which we find resemblances in certain ordinary Ruminants, but not in the giraffe. Its place in the Ruminant series is between the deer and antelope. These extensive families are respectively distinguished, not only by the nature of their horns, but by a well-marked anatomical character: the gall-bladder is present in the antelopes, and not in the deer. In three giraffes lately dissected in this country a gall-bladder was present in one, and not in the other two. In that in which it was discovered it presented an abnormal structure, being bifid at the fundus, and divided into two compartments. We may infer, therefore, that in this part of their organization, as in the structure of their horns, the giraffes are more nearly akin to the deer tribe than to the antelopes. Yet it must not be forgotten that while we search in vain among the *Cervidæ* for an equine mane and tufted tail, such as ornament the giraffe, we find both these peculiarities combined in the gnu among the antelopes. A giraffe more than two thirds grown will eat daily in confinement eighteen pounds of clover-hay, and eighteen pounds of a mixed vegetable diet, consisting of carrots, mangel-wurzel, barley, split beans, and onions; and will drink four gallons of water. They copulate in March. The female has four inguinal udders: she brings forth one young one at a birth; and the period of gestation is fifteen months. The new-born giraffe measures six feet from the fore-hoofs to the top of the head. In a few hours it is able to follow the dam. It resembles the mature animal in the markings of the hide. The first giraffe known to have been produced in captivity was brought forth in June, 1839, at the gardens of the Zoological Society of London.

GI'RASOL. A milk-white or bluish opal, which, when turned to the sun or any bright light, reflects a reddish colour; hence its name, from gyro, *I turn*, and sol, *the sun*.

GI'RDER. (Sax. ᵹẏꞃꝺan, *to inclose.*) In Architecture, a principal beam in a floor for supporting the binding or other joists, whereby their bearing or length is lessened. Perhaps so called because the ends of the joists are inclosed by it.

GI'RDLE. (Anglo-Sax. girdan, *to encircle.*) A belt or band of leather or some other substance used in girding up the loins. The girdle (Gr. ζωνη, Lat. cingulum) was in use among the Hebrews, Greeks, and Romans, for various purposes more or less important. By the Hebrews it was worn chiefly upon a journey, and sometimes as a mark of humiliation and sorrow; and by the Greeks and Romans it was used as a military ornament. Hence in the Latin phraseology *cingulum deponere* denoted "to quit the service." To deprive a soldier of his girdle was the deepest mark of ignominy with which he could be branded; and even among the civilians, who always wore a girdle over the tunic to render their motions unembarrassed, the want of this appendage was considered strongly presumptive of idle and dissolute propensities. In conformity with this opinion, or perhaps in allusion to the occasional substitution of the girdle for the purse among the Romans, Horace has affirmed that "you may do what you please with him who has lost his girdle,"—

Ibit eo quo vis qui zonam perdidit.

Zonam solvere virgineam was a well-known phrase appropriated to the marriage ceremony. To Venus was attributed by the poets the possession of a particular kind of girdle, called *cestus*, which was said to have the power of inspiring love.

It was formerly the custom in England for bankrupts or other insolvent persons to put off and surrender their girdles in open courts.

GIRO'NDE, THE. In French History, a celebrated political party during the Revolution; its members were termed Girondists or Girondins. The name was derived from that of the department La Gironde (in which Bordeaux is situated), which sent to the legislative assembly of 1791, among its representatives, three men of eloquence and talent (Guadet, Gensonné, Vergniaud), who were among the chief leaders of the party. Its principles were republican. During the continuance of that assembly the Girondists formed a powerful, but not always consistent party. Out of these Louis XVI. chose his republican ministers in the beginning of 1792. But after the massacres of September in that year the party in general withdrew from all connection with the Jacobins, and approximated towards the Constitutionalists. In the Convention the Girondists at first commanded a majority, but on the king's trial they were much divided; and, being pressed by the violence of the sections of Paris, they were at length expelled the assembly: thirty-four of them were outlawed, and finally twenty-two of their leaders guillotined (7th and 31st October, 1793), while a few escaped, and others put an end to themselves. Perhaps the most celebrated member of the Gironde party was a lady, Madame Roland, the wife of the minister of that name, who was executed when the party fell, and whose writing — the *Appel au Peuple* — bears all the stamp of that high republican enthusiasm which characterized them. (The remaining part of her memoirs is of suspicious authenticity.) Various apologies and eulogies of the party have appeared. Its members were not without high qualities; but its counterpart will be found in all revolutions, in that body of men of high theoretical views of social reform and little practical knowledge, who are commonly lifted into power by supporters more energetic but less high-principled than themselves at one turn of affairs, and sure to be thrust down in a short time by their own former adherents. (See particularly the

histories of Mignet and Thiers, for general views on the subject; for details, the *Histoire Parlementaire* of Messrs. Buchez and Roux, who are perhaps too unfavourable to the party.

GIRT LINE. A rope to lift the rigging up to the mast head on first rigging the ship.

GIVEN, in Geometry, signifies something that is known. Thus, a straight line is given in *position* when we know the situation of two points through which it must pass; and it is given in *magnitude* when we know its length. A triangle is given in *species* when we know the magnitude of each of its three angles, and a circle is given when we know its centre and radius.

GLA'BROUS. (Lat. glaber, *smooth.*) A term applied in Mammalogy to those parts of the surface of a quadruped which are naturally devoid of hair; and in Entomology, when a surface is smooth and devoid of hair or pubescence.

GLA'CIERS. (Fr.) The name given to the immense masses of ice which accumulate on the peaks and slopes, and in the upper valleys, of lofty mountains. The phenomena of glaciers form one of the most interesting subjects of scientific investigation, whether we regard their formation, structure, or appearance. In all parts of the globe they have the same general characteristics; but though the glaciers of other countries have often been described by geographers and naturalists, it is chiefly in respect to those of Switzerland that we possess detailed information. In that country, as indeed in every other, those parts of the mountains that rise above the line of congelation are covered with perpetual snow, which being partially thawed during the summer months, is on the approach of cold converted into ice, thus constituting what is called a *glacier*. The ice so formed descends along the slopes of the mountains into the valleys, by which their ridges are furrowed, where it accumulates into vast beds or fields; presenting, where the descent is gradual, a very level surface, and with few crevices, but where there is a rapid or rugged declivity, being rent with numerous chasms *, and covered with elevations rising from 100 to 200 feet. Though the snow line on the Alps is found at an elevation of about 8000 feet above the level of the sea, some of the glaciers descend so far downward that their lower extremity is not more than 3500 feet above it. This is particularly the case in the valley of Chamouni, where the singular spectacle is presented of huge pyramids of ice of a thousand fantastic shapes in juxtaposition with the most luxuriant pastures, or towering in majestic grandeur in the midst of verdant forests. The principle of the descent of the glaciers is twofold: viz. one of a slow and gradual character, like the dunes of France, by which a progressive movement of about twenty-five feet annually is effected; the other of a rapid and impetuous kind, in which a portion of the ice having been disrupted from the main body glides down the mountain's side, accumulating as it goes, and precipitating into the valleys beneath immense stones, fragments of rock, and other substances to which it had adhered. Philosophers and naturalists have attributed this downward movement of a glacier to various causes; but by far the most prevalent opinion respecting it is that of Saussure, who maintained it was nothing more than a slipping upon itself, occasioned by its own weight. On the other hand, M. Agassiz ascribes this motion to the expansion of the ice, resulting from the congelation of the water which has filtered into it and penetrated its cavities; while Mr. R. Mallet is inclined to attribute it to the hydrostatic pressure of the water which flows at the bottom and makes rents in the mass. When the debris which the glaciers accumulate in their descent has been deposited in the valleys, it constitutes what in Savoy is termed their *moraine* or border, an essential feature in the Alpine glaciers. These borders present every variety of aspect; but their most usual appearance is that of unfathomable bogs or morasses wholly destitute of vegetation, and in many instances fraught with infinite peril to the traveller. They are generally arranged in long ridges or mounds from 30 to 40 feet high; and being often two, three, or even four in number, resemble so many lines of entrenchment.

The Alpine glaciers occupy a superficial extent of 1484 square miles. From Mont Blanc to the borders of the Tyrol there are reckoned about 400, of which the greater number varies from 10 to 15 miles long, and from 1 to 2½ broad; their mean vertical thickness ranges from 100 to 600 feet. Besides the grand and picturesque appearance they present externally, their lower extremities are sometimes excavated by the melting of the ice into the form of immense grottoes, adorned with the finest stalactic crystallizations, whose brilliant azure tints are reflected on the foaming streams and torrents which generally issue from these caverns, forming altogether so beautiful and imposing a picture as to defy the most faithful pencil to portray it adequately. The glacier ice does not resemble that found in ponds and rivers: not being formed in layers, but consisting of small grains or crystals of congealed snow, it has neither the compactness, the solidity, nor the transparency of river ice; and though "every single crystal seems perfectly white, the whole mass is of a blue colour, passing through every variety of shade, from the most feeble sky-blue to that of the lapis lazuli." From the large accessions of snow and ice which the glaciers receive, especially in winter, it might reasonably be conjectured that they must be gradually increasing in size, and would consequently in the course of time break through their usual limits and overwhelm the cultivated lands of the surrounding country. This, however, is by no means the case. It no doubt often happens that on some occasions the glaciers are observed to descend lower than usual; but, when this takes place, the warm atmosphere of the lower valleys into which they have advanced (whose temperature rises in proportion to their depression) operates with such powerful effect in reducing their bulk, that they are invariably found to recede proportionably. Thus nature has established a compensating process, by which an effectual though simple check is administered to the encroachment of the glaciers upon the cultivated lands of the Alpine valleys. There are various other phenomena connected with the glaciers, for a full account of which the reader is referred to *Saussure's Voyage dans les Alpes*. See also *M'Culloch's Geographical Dict*., art. "Alps;" *Penny Cyclo*., art. "Glacier;" and arts. ICEBERG and MORAINE in this work.

* "These chasms are frequently many feet wide and more than 100 deep. Their formation, which never takes place in winter, but is frequent during summer, is accompanied with a loud noise resembling thunder, and a shock which makes the adjacent mountains tremble. They are subject to change every day, and almost every hour; and it is this circumstance that renders the ascent of the glaciers so dangerous to travellers."— *Geog. Dict*., art. "Alps."

GLA'CIS. In Fortification, a sloping bank of earth, extending from the parapet of the counterscarp to the level country.

GLADIA'TORS. (Lat. gladiatores; from gladius, *a sword.*) Sword players, who were originally employed to fight at the funerals of illustrious Romans, in order to appease their manes by the effusion of blood. They were subsequently introduced into the public amphitheatres, and became one of the most favourite spectacles of the Roman people. The gladiators were either captives or condemned criminals, or else people of the lowest rank, who served for hire, the profession being considered one of the greatest infamy. In spite of this, however, under some of the emperors, persons of the first families, who had enjoyed the highest honours of the state, entered the arena, either at the command of the despot, or in order to gratify him; and even females of patrician blood, in some instances, followed their example. Gladiators did not merely use the sword, as their name strictly implies, but were armed in various ways. (*See* MIRMILLO and RETIARIAN.) The gladiators were, in general, desperate and ruffian characters; and considerable bodies of them were sometimes kept in the pay of wealthy and turbulent citizens, or hired as bullies. Perhaps the best exposition of the opinion of the more philosophical Romans on the subject is thus given by Cicero:—"Crudele gladiatorum spectaculum et inhumanum nonnullis videri solet: et haud scio an non ita sit, ut nunc fit: cum vero sontes depugnabant, auribus fortasse multa, oculis quidem nulla poterat esse fortior contra dolorem et mortem disciplina." (*Tusc. Quæst.* 2.) It is commonly, but inexactly said, that the shows of gladiators were put a stop to by the Christian emperors. They certainly had not ceased in A. D. 404, and probably not before the conquest of Italy by the Goths. (Beugnot, *Destruction du Paganisme en Occident*, book ix. ch. 2.)

GLA'DIUS. (Lat.) The name of the internal horny plate of the calamaries, which was called by the Greeks ξιφος, or the sword.

GLANCE COAL. *See* ANTHRACITE.

GLAND. In Anatomy. This term is applied to those organs of the body in which *secretion* is carried on, and which appear to consist of a congeries of blood-vessels, nerves, and absorbents: they are frequently distinguished according to their secretion, into mucous, sebaceous, lymphatic, and lachrymal; or, according to their form and texture, into simple, compound, conglobate, and conglomerate.

GLANDS, LENTICULAR. In Botany, a term invented by Guettard to denote brown oval spots found upon the bark of many plants, especially willows, indicating the points from which roots will appear if the branch be placed in circumstances favourable to their production. They are, in fact, nothing but protuberances formed by the pressure upon the epidermis of subjacent roots attempting to pierce through it.

GLASS. (Germ.) A transparent, impermeable, and brittle substance. There are several varieties of glass, applicable to different purposes, and differing in their composition. Its essential ingredients are silica and potash or soda, to which a variety of other substances are occasionally added; one of the most common and important of which is oxide of lead, by which the fusibility and density of the glass is increased, so that it is more easily worked, and more brilliant, especially when ornamented

by cutting: of this latter description is the glass called *flint glass*, used for decanters, drinking glasses, chandeliers, &c. It consists of about 52 parts of silica, 34 of oxide of lead, and 14 of potash. Chemically speaking, therefore, it is a double silicate of potash and lead, containing 12 atoms of silica, 1 of potash, and 1 of oxide of lead. *Crown glass*, used for windows, is a compound of silica and soda, with a portion of lime. *Green bottle glass* is made of a mixture of sand with impure wood ash, kelp, and a portion of brick clay. These kinds of glass are manufactured by the operation called *blowing*. *Plate glass*, invented by Abraham Thwart, was first manufactured in Paris in 1688. It may be composed of 300 lbs. of fine sand, 200 of soda, 30 of lime, 32 oz. of black oxide of manganese, 3 of cobalt azure, and 300 lbs. of fragments of good glass. These materials, when in perfect fusion, are poured upon a hot copper plate; the mass is then rolled out, annealed, and afterwards polished by grinding with sand, emery, and colcothar. The difficulty of producing a perfect plate, without specks, bubbles, or waves, together with the risk of breakage, render large plates very expensive: on account of their necessary thickness they are also very heavy.

The manufacture of glass is one of the highest beauty; and considering the worthlessness of the materials of which it is made, and the various purposes of a useful, ornamental, and scientific nature which it subserves, may be regarded as perhaps the most important in the history of inventions. The period of its invention is involved in great obscurity; but if we believe Pliny, we are indebted for this necessary of life, as we are for the gift of letters, to the Phœnicians. The popular opinion upon this subject refers the discovery to accident*; but, as Dr. Ure has observed, there were circumstances in the ancient arts likely to lead to it, such as the fusing and vitrifying heats required for the formation of pottery and for the extraction of metals from their ores. But, be this as it may, the Egyptians were certainly acquainted with the art of glass-making; for in some nomes glass beads have been found coloured with a metallic oxide, and pieces of glass have been discovered in the ruins of Thebes. (See M. Boudet, *Desc. de l'Egypt*, vol. ix.; *Aul. Mémoires*.) In Strabo and Pliny's time, the inhabitants of Sidon and Alex were famed for the production of beautiful glass, which they cut, engraved, gilt, and stained of the richest colours, in imitation of precious stones, and exported to all parts of the then civilized world. At Rome, too, glass was manufactured into various articles of convenience and ornament; and so great was the luxury of this article, or so exquisite its manufacture in those days, that Nero is reported to have given 6000 sesterces for two glass cups. For a long time Venice is said to have excelled all the countries of Europe in this manufacture; of which, indeed, it may be said to have enjoyed a monopoly till about the middle of the 17th century, when the invention of blown mirror glass by Colbert gave France a decided superiority over its rival. At what period the manufacture of glass was introduced into England is not precisely known; but there can be no doubt that till near the close of the 17th century, this country was obliged to have recourse to foreigners for the supply of the common article of drinking glasses. In 1673, the Duke of Buckingham materially improved the fabrication of British plate-glass by bringing over several Venetian artisans to the works at Lambeth, which were under his patronage; and the manufacture was still further improved by the arrival of the French refugees subsequently to the revocation of the edict of Nantes. The above works, however, were soon abandoned; and it was exactly one century (1773) later that the first establishment of magnitude for the production of plate-glass was formed, under the title of "The Governor and Company of British Cast Plate-Glass Manufacturers." This company was incorporated by act of parliament, and soon after erected works on an extensive scale at Ravenhead, near Prescot, in Lancashire, which have continued in constant operation down to the present time. Since that period immense improvements have been made in the manufacture of every species of glass throughout all the countries of Europe, though the art may be said to have reached perfection only in England and Bohemia.

The application of glass to the glazing of windows is of comparatively recent introduction into dwelling-houses, though it was general in churches and other public buildings as early as the third or fourth century. In London, this manufacture was first begun in 1557; but that the use of window-glass was by no means universal even twenty years later, is evident from the fact that at Alnwick Castle, the residence of the Duke of Northumberland, the glass casements used at that period to be taken down in the absence of the family, to preserve them from accident.

* Pliny ascribes the origin of glass to the following accident: — A merchant-ship laden with natron being driven upon the coast of the mouth of the river Belus in tempestuous weather, the crew were compelled to cook their victuals ashore; and having placed lumps of the natron upon the sand as supports to the kettles, found, to their surprise, masses of transparent stone among the cinders.

In Scotland, even in the early part of the last century, glass was seldom seen in the windows of country houses; and a few years previously, even in the royal palaces and the town houses of the nobility, the windows of the upper stories alone were furnished with it. Since that period, however, a mighty change has been effected; for now even the windows of the meanest cottage in Great Britain are, almost without exception, supplied with glass, which, as Mr. M'Culloch has well observed, ought rather to be considered as a necessary of life, than as the most elegant and useful of conveniences.

In 1833, the number of establishments for the manufacture of every description of glass in the United Kingdom was 126, of which 106 were in England, and the remainder equally divided between Scotland and Ireland. The principal seats of the manufacture are beyond all comparison Newcastle and South Shields; but it is also carried on with great success at Stourbridge, Dudley, Liverpool, Bristol, and Warrington, and to a considerable extent in Leeds, Manchester, and London. The value of the glass annually produced in the United Kingdom is estimated at 2,000,000*l.*; and the workmen employed in the different departments at upwards of 50,000. In 1837, the total gross revenue derived from the glass duties amounted to 903,856*l.* 12*s.* 10*d.*; of which England produced 837,277*l.* 14*s.* 9*d.*, Scotland 56,220*l.* 4*s.* 11*d.*, and Ireland 10,378*l.* 13*s.* 2*d.* In no branch of manufacturing industry is the prejudicial effect of high duties upon the consumption of articles of convenience more strikingly illustrated than in the history of the duty upon glass in this country. It would be out of place here, however, to enter upon this subject; and we can only refer the reader for full information to the *Commercial Dictionary*, and the *Statistics of the British Empire*, vol. i. p. 715. 2d edit.

GLASS PAINTING. In Painting. The method of staining glass in such a manner as to produce the effect of representing all the subjects whereof the art is susceptible. A French painter of Marseilles is said to have been the first who instructed the Italians in this art, during the pontificate of Julius II. It was however, practised to a considerable extent by Lucas of Leyden, and Albert Durer. The different colours are prepared as follows: — *Black* is composed of two thirds of iron scales or flakes, and the other third of small glass beads, or a substance called *roccaglia* by the Italians. *White* is prepared from sand, or small white pebbles, calcined, pounded, and then ground finely; one fourth part of saltpetre is added, and the mixture is then again calcined and pulverized: when dyed a little gypsum or plaster of Paris is added. *Yellow* is formed from leaf silver ground and mixed in a crucible with saltpetre or sulphur; then ground on a porphyry stone; and lastly ground over again with nine times the quantity of red ochre. *Red*, one of the most difficult of the colours to make, is prepared of litharge of silver and iron scales, gum Arabic, ferretta, glass beads, and bloodstone, in nearly equal quantities. Experience alone will command success in making this colour. *Green* is formed from æs ustum one ounce, the same quantity of black lead, and four ounces of white lead, incorporated by the action of fire. When calcined a fourth part of saltpetre is added, and after a second calcination a sixth part more; after which a third coction is made before using it. *Azure*, *purple*, and *violet* are prepared in a similar manner to green, omitting the æs ustum, and in its stead using sulphur for azure, perigneux for purple, and both these drugs for violet. *Carnations* are compounded colours, are calcined, and mostly mixed with water; and must be finished part by part, and each with great despatch, before the plaster dries, and there is little opportunity for blending. The lights cannot be heightened; but the shadows may, when they begin to dry, be a little strengthened. Promptitude and facility in execution are the great requisites for this method of painting. *See* Cartoon.

GLAU'BER'S SALT. Sulphate of soda, originally made by Glauber, in his process for obtaining muriatic acid, by distilling a mixture of common salt and sulphuric acid.

GLAU'COLITE. (Gr. *γλαυκος*, *blue.*) A mineral of a bluish green colour, found near the lake Baikal, in Siberia; it is a silicate of alumina and lime.

GLAUCO'MA. (Gr. *γλαυκος*.) A disease of the eye, supposed to arise from dimness of the vitreous humour, and giving it a blueish green colour.

GLAUCO'PIS. (Gr. *γλαυκος*, and *ωψ*, *an eye.*) A genus of Passerine birds established by Forster, and including certain species remarkable for the presence of fleshy wattles attached to the base of the beak; whence they are commonly termed "wattle-birds." Temminck characterizes the genus as follows: — Bill moderate, strong, and thick, with the base enlarged towards the commissure; upper mandible convex, vaulted, curved towards the end, and without any notch; lower mandible following the curvature of the upper, straight below, hidden in part by the sides of the upper mandible. Nostrils basal, lateral, round, partially closed by a large

membrane, and entirely hidden by curled feathers advancing from the forehead. Feet robust, the tarsi longer than the mid-toe; toes nearly of the same length; the base of the inner toe, and nearly the whole of the outer toe, attached to the middle toe. Wings short; the first quill short, the three following graduated, and the fifth the longest. Tail long and graduated.

GLAU'COUS. Sea green; a term used in describing the colour of bodies, to denote a dull green passing into blue. Also used in describing the polish of bodies, to denote their being covered with a fine bloom of the colour of a cabbage leaf. Glaucescent is the diminutive of this.

GLAU'CUS. (Gr. *γλαυκος, blue.*) In Grecian Mythology, the name of a marine deity, the son, according to some of the genealogists, of Neptune, and one of the Näiads; according to others, of Polybius and Alcyone. He enjoyed the power of prophecy.

In Zoology, *Glaucus* is the name of a genus of Nudibranchiate Mollusks, remarkable for their beautiful azure tint. The species of *Glaucus* are found in the warmer latitudes floating in the open sea.

GLEA'NING. (Fr. glaner.) The practice of collecting corn left in a harvest field after the harvest has been carried, which (Levit. c. 19., Deut. c. 24.) appears by the Mosaic law to have been allowed to the poor. The right of the poor to glean is, however, not admitted in the English common law.

GLEBE. (Lat. gleba, *arable soil.*) In Law, church land; usually taken for that which is annexed to a parish church of common right, and belongs to the parson or vicar.

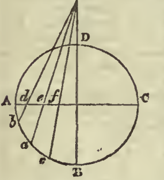
GLEE. In Music, a composition for voices in three or more parts. The subjects of the words are various, being gay, grave, amatory, pathetic, or bacchanalian. It may consist of only one movement, but usually has more.

GLEE-MAN. (From the Anglo-Saxon gleo, glig, &c. signifying *music.*) Itinerant minstrels were so called by the Saxons: their appellation is translated joculatores by the Latin writers of the middle ages. The name appears to have been supplanted by the Norman minstrel, shortly after the Conquest.

GLIRES. (Lat. glis, *a dormouse.*) The Linnæan name of the order of Mammalia distinguished by two long chisel-shaped incisors in each jaw. *See* RODENTIA.

GLOBE. A round body, or sphere; a term commonly applied to the earth. The term *artificial globe* is more particularly used to denote a globe of metal, plaster, paper, &c., on the surface of which a map of the earth or of the celestial constellations is delineated, with the principal circles of the sphere. In the former case it is called the *terrestrial*, in the latter the *celestial globe*. Artificial globes are used for the purpose of conveying to children the first ideas of the figure and rotation of the earth, of latitude and longitude, and the situation of places with respect to each other, and to the sun at the different seasons of the year. It is usual to employ them also for the purpose of solving mechanically a few elementary problems of astronomy, relative to the difference of the hour of the day at different places, the times of the rising and setting of the sun, the limits of the visibility of eclipses, &c. The answers, however, which can be found to questions of this nature, by means of ordinary globes at least, can only be regarded as rude approximations; and hence the use of globes should be limited to general explanation.

GLO'BULAR CHART. A delineation of the terrestrial surface, or any part of it, on a plane, according to the principles of the *globular projection*. Let A B C be the hemisphere to be projected, and A C the plane of projection; in order to make a globular projection, the eye is placed at the point E in the straight line B D, which passes through the pole B and the centre of the sphere, and at a distance D E above D equal to the sine of 45°. The peculiar advantage of this projection is that equal arcs, *a b*, *a c*, of great circles, are represented by straight lines *d e*, *e f*, which are nearly equal. If the plane of projection is the equator, the different meridians will be represented by straight lines, and the parallels of latitude by concentric circles. But in general the projection is made on a meridian, in which case the projections of the other meridians are ellipses. The globular projection was first proposed by Lahire. *See* MAP, PROJECTION.



GLO'BULA'RIA'CEÆ. (Globularia, one of the genera.) A small natural order of shrubby or herbaceous Exogens, inhabiting the hot and temperate parts of Europe. Placed by Jussieu and De Candolle near to *Primulaceæ;* but in greater affinity with *Dipsaceæ*, with which they agree in most respects, differing from them only in having a superior ovary. Their sensible properties are bitter tonic and purgative.

GLOBULAR SAILING. *See* NAVIGATION.

GLO'BULINE. A term given by Kieser to the green globules lying amongst the cells of cellular tissue. This word has been applied by Turpin, a French phytotomist, to all minute vesicular granules of a vegetable nature, which he considers the organic elements of vegetation. It is either cellular or vesicular tissue in a young state and disintegrated, or granules of starch or particles of colouring matter collected into microscopical balls.

GLO'RY. (Lat. gloria.) In Painting and Sculpture, a circle, either plain or radiated, surrounding the heads of saints, &c., and especially of our Saviour. The term glory is used in the sacred writings in various senses, all of which, however, may be easily deduced from the original meaning of its Hebrew equivalent, which signifies *weight*. Thus *the glory of God* means all those attributes and qualities which give him *weight* in our eyes, or inspire us with reverence. (See *Taylor's Concordance*.)

GLOSS. (Gr. *γλῶσσα, tongue.*) In the Rhetoric of Aristotle, this word is used in the sense of a foreign, obsolete, or otherwise strange idiom; which, judiciously employed, he reckons among the ornaments of style. From the sense of "something requiring interpretation" the word came to mean the interpretation itself; strictly, of a single word or phrase. In the twelfth century, the comments or annotations of learned jurists on passages in the text of the Roman law were denominated glosses; when these extended to a running commentary, they were termed an apparatus. The glosses were collected by Accursius in the 13th century, and from that period they formed for a long time a body of authority reckoned equal or even superior to the text itself.

GLO'SSARY. (Lat. glossarium.) A dictionary of difficult words and phrases in any language or writer; sometimes used for a dictionary of words in general. Of all the works published under the title of glossary, the most celebrated by far is the *Glossarium Mediæ et Infimæ Latinitatis* of Du Cange. The best edition of this learned and admirable work is that edited by Carpentier, in 6 vols. folio, 1733—1736. Carpentier's *Supplement*, in 4 vols. folio, 1766, is an indispensable addition.

GLO'TTIS. (Gr. *γλωττα, the tongue.*) The superior opening of the larynx or windpipe.

GLOVES. (Anglo.Sax. glof.) Well-known articles of dress used for covering the hands. The practice of covering the hands with gloves has prevailed among almost all the nations of the earth from time immemorial, and is common at once to the rude Tartar, who seeks by their means to protect himself from cold, and to the refined European, with whom their use is an emblem of luxury. (*Gough. Sep. Mon.* i. p. 185.) In the middle ages, gloves constituted a costly article of dress, being often highly decorated with embroidery and richly adorned with precious stones. In the age of chivalry it was usual for the soldiers who had gained the favour of a lady to wear her glove in his helmet; and, as is well known, the throwing of a glove was the most usual mode of challenging to duel. This latter practice prevailed so early as the year 1245. *Matthew Paris's History*. (See the *Penny Cyc.*, and the authorities there referred to.)

GLOW-WORM. *See* LAMPYRIS.

GLUCI'NIUM. The metallic base of the earth glucina, discovered by Vauquelin in 1798, and hitherto only found in three rare minerals,—the emerald, beryl, and euclase. The name is derived from *γλυκυς, sweet*, in consequence of the sweet taste of its salts. The metal, which is of a dark grey colour, was first obtained in 1828 by Wöhler; he procured it by acting upon the chloride of glucinium by potassium. The equivalent of glucinium is 18, and glucina consists of 18 glucinium + 8 oxygen.

GLUE (Lat. gluten), is prepared from the clippings of hides, hoofs, &c. These are first washed in lime water, and afterwards boiled and skimmed; the solution is then strained through baskets, and gently evaporated to a due consistency; then cooled in wooden moulds, cut into slices, and dried upon nets. Good glue is semitransparent, deep brown, and free from spots and clouds. When used it should be broken in pieces, and steeped for twenty-four hours in cold water, by which it softens and swells; the soaked pieces are then melted over a gentle fire, or, what is better, in a water bath, and in that state applied to the wood by a stiff brush. Glue will not harden in a freezing temperature, the stiffening depending upon the evaporation of its superfluous water. The chemical properties of glue are those of an impure *gelatine*.

GLU'TEN. (Lat.) The viscid elastic substance which remains when wheat flour is wrapped in a coarse cloth, and washed under a stream of water, so as to carry off the starch and soluble matters. Gluten exists in many grains, and occasionally in other parts of vegetables; but it is a characteristic ingredient in wheat, giving wheat flour its peculiar toughness and tenacity, which particularly fits it for the manufacture of bread, and for viscid pastes, such as macaroni and vermicelli. There is generally more gluten in the wheat of warm climates than of cold; hence the excellence of that grown in the

south of Europe for the manufactures just mentioned. Gluten contains nitrogen, and has consequently been called the vegeto-animal principle on this account: it yields ammonia when subjected to destructive distillation, and the vegetables which contain it give out a peculiarly disagreeable odour during their putrefaction.

GLU'TEUS. (Gr. γλουτος, *the buttocks.*) The large and thick muscle upon which we sit, and which serves to extend the thigh by pulling it directly backwards. It also assists in its rotatory motion.

GLU'TTON. The name of a carnivorous plantigrade quadruped (*Gulo arcticus*); also applied by some micrographers to a diaphanous species of *nais*.

GLY'CERINE. (Gr. γλυκυς, *sweet.*) A sweet substance formed in the process of saponification. It was originally observed in the formation of common plaster by boiling oil with oxide of lead and water.

GLYCY'RRHIZIN. The peculiar saccharine matter of the root of *Glycyrrhiza glabra*, or common liquorice.

GLYPH. (Gr. γλυφω, *I carve.*) In Architecture, a vertically sunken channel. From their number those in the Doric order are called *triglyphs*.

GLY'PTIC. (Gr. γλυφω.) In Sculpture, a term denoting the art of carving on stone or any other hard substance.

GLY'PTODON. (Gr. γλυφω, and οδους, *a tooth.*) The name of an extinct gigantic quadruped belonging to the family of Armadillos (*Dasypodidæ*), and covered, like them, with a tesselated osseous armour. It is distinguished from the existing armadilloes not only by its size, which equals that of the rhinoceros, but by its teeth, which are longitudinally fluted, whence its generic name.

GLY'PTOTHE'CA. (Gr. γλυφω, and θηκη, *deposit.*) A building or room for the preservation of works of sculpture; a word adopted by the Germans, as in the instance of the celebrated Glyptothek at Munich.

GNAT. *See* Culex.

GNATHI'DIA. (Gr. γναθος, *a jaw.*) A technical term in Ornithology for the lateral parts or rami of the mandible or lower jaw, which are joined to the cranium behind, and meet in front at a greater or less angle.

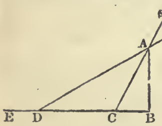
GNA'THOTHE'CA. (Gr. γναθος, and θηκη, *a sheath.*) In Ornithology, the horny or cutaneous integument of the beak.

GNEISS. A species of granite, which from excess of mica is generally of a lamellar or slaty texture. It is a German miner's term.

GNOME. A name given by the fanciful writers of the Cabalistic school to that class of their supposed elemental spirits which inhabit the earth. Their name is more properly *Gnomons;* derived from the Greek γνώμων, *knowing, cunning.* (See *Darwin's Botanic Garden.*)

GNO'MIC POETS. (Gr. γνωμη, *a sentence or opinion.*) Greek poets, whose remains chiefly consist of short sententious precepts and reflections, are so termed in classical bibliography. The principal writers of this description, of whom a few fragments are extant, are Theognis and Solon, who lived in the 6th century before the Christian era. With them Tyrtæus and Simonides are joined by Brunck in his edition (*Gnomici Poetæ Græci*, Argent, 1784), although these writers have little of a gnomic character. The metre of these poets is elegiac.

GNO'MON. (Gr. γνωμων.) In Astronomy, an instrument for measuring the lengths of shadows, and thereby determining the altitudes of the sun. Let A be the top of a vertical style, column, or pillar, or a small hole in a wall A B, the height of which above the horizontal line B E is accurately known; a ray of solar light coming in the direction S A reaches the ground at C, and the length of the shadow projected by the gnomon is B C. Now, as the length of B C can be accurately measured, and as A B is known, and the angle at B is a right angle, it is easy to find by the rules of plane trigonometry the angle A C B, or the sun's altitude. Suppose S C B thus found to be the sun's meridian altitude on the day of the summer solstice, and S′ D B his meridian altitude on the day of the winter solstice; then half the difference between these two altitudes is the obliquity of the ecliptic, or the sun's greatest declination. And when the sun's declination and meridian altitude are both known, the latitude of the place of observation is likewise determined. In this way Pytheas, in the time of Alexander the Great, found at Marseilles the ratio of the height of the gnomon to the meridional shadow on the day of the solstice to be 120 to $41\frac{4}{5}$ (*Montucla*, vol. i. p. 191.), whence the obliquity of the ecliptic is concluded to have been at that time about 23° 49′.



Gnomons were probably the first astronomical instruments; and they appear to have been much in use among the Egyptians, the Chinese, and even the Peruvians. (*Goguet, Origine des Loix.*) The Egyptian obelisks are supposed to have been intended as gnomons. It is evident that observations of this kind cannot give the sun's altitude with much exactness. The shadow is never so well defined that its limits can be ascertained with astronomical precision; besides, the observation requires to be corrected for parallax, refraction, and the sun's semi-diameter, — elements which can only be determined by means of instruments of a very superior description to the gnomon, and which, consequently, render the latter useless. The astronomer Ulug-Beg, about the year 1437, erected a gnomon at Samarcand, the height of which was 165 Paris feet

Gnomon, in Dialling, is the style of the dial, the shadow of which marks the hour. It is placed so that its straight edge is parallel to the axis of the earth's rotation.

Gnomon. In Geometry, the part of a parallelogram which remains when one of the parallelograms about its diagonal is removed; or the portion of the parallelogram composed of the two complements and one of the parallelograms about the diagonal. The term is seldom used, excepting in *Euclid's Elements.*

GNOMO'NIC PROJECTION. The representation of a hemisphere on a plane touching it at the vertex, the eye being placed at the centre of the sphere. In this projection all great circles of the sphere are projected into indefinite straight lines, small circles parallel to the plane are projected into circles, and those which are oblique to it into ellipses or hyperbolas. *See* Projection.

GNOMONICS. The art of constructing dials. *See* Dialling.

GNO'STICISM. (Gr. γνωσις, *knowledge.*) A philosophical system of religion which prevailed in the East during the four first centuries of our era, and exercised great influence upon Christian theology, giving birth to numerous and widely diffused heresies, and insinuating itself under a modified form even into the writings of the most orthodox fathers. The origin of the system is involved in considerable obscurity: in its leading principles it seems to point to the oriental philosophy as its genuine parent; but it is objected to this solution that the fathers refer it, together with the errors similarly introduced by Platonism, to a Greek origin, and appeal to the cosmogonies of Hesiod and others as the real exemplars from which it is imitated. It is to be remarked, however, that the fathers were universally ignorant of the oriental philosophy; from which we may conclude that their opinion upon such a point is not necessarily decisive. A modern solution conceives Alexandria to have been the central point to which the speculations of the Greeks and the orientals converged, and from whence they frequently re-issued, after having undergone the process of fusion into a common mass. It is certain that Alexandria was, during the time we have spoken of, a celebrated resort of Gnostic opinions, both within and without the church.

The grand principle of this philosophy seems to have been an attempt to reconcile the difficulties attending upon the existence of evil in the world. Evil, it was supposed, being the contrary of good, must be contrary to, and therefore the opponent of, God: if the opponent of God, then independent of him and coeternal. From the many imperfections which are involved in all outward and sensible objects, it was held that matter must contain in itself the principle of all evil. The human soul, on the contrary, which aspires after and tends to a higher and more perfect development, was held to be the gift of the Supreme Deity, imparted to man for the sake of combating against the material principle, and with the prospect of finally subduing it. From the Supreme God on the one hand, and matter on the other, succeeding philosophers produced various fanciful genealogies of superior intelligences, under the name of Æons, — a Greek word, signifying properly periods; thus representing these divinities themselves by a name expressive of the time and order of their generation, much as in our current language the terms reign, or government, are frequently put for the king or ministers governing. The Demiurgus, who formed the world out of matter, appears to have been an Æon derived from the evil principle. He was also the God of the Old Testament, who was considered by the Gnostics to be an object of aversion to the One Supreme God, to counteract whose machinations the Æon Christ was sent into the world. This is the earlier and simpler system, which is attributed to Simon Magus: the number of the Æons was fancifully multiplied in later times, and an extravagant theory of morals founded upon the system The object of these principally was, as may be supposed, to depreciate the honour due to the body, as being a part of matter, and to elevate the thinking faculty, or at least to remove it from all consideration of worldly things. The Gnostics imagined that by assiduous practice of certain mental and bodily austerities they could obtain an intuition of the divine nature, and dwell in communion with it; and this part of their system is adopted to a considerable extent by Clemens Alexandrinus, whose opinions, as expressed in his *Pædagogus*, are very similar to those of a Pietist of more modern times.

The Gnostics split in process of time into various sects,

distinguished rather by the different cosmogonies they invented, than by any variation in principle. Of these the principal were founded by Carpocrates, Basilides, Tatian, and Valentinus. The system did not survive the 4th century. The Christians seem sometimes to have adopted the general designation of Gnostics. (See *Burton's Bampton Lectures; Neander; Mosheim*, vol. i. (Transl.) p. 133, &c.; Gieseler, *Text-Book of Eccl. Hist.* i.; *Riddle's Christian Antiquities*, p. 133.)

GOAT, the English name for the well-known ruminant of the genus Capra. The goat is characterised by its long horns, which are rounded posteriorly, angular on the anterior edge; transversely rugose, and rise at first perpendicularly, afterwards bending outwards and a little backwards. It is clothed by long hair, which, in the Cashmere breed, is soft and fine, and forms the staple of the celebrated shawls of that name. Beneath the long hair is a soft wool. The female produces two kids at a birth, which derive their nourishment from two teats supported on a large pendant udder. The period of gestation is five months. The milk of the goat is less apt to curdle on the stomach than that of the cow, and is thus better adapted for the weak and consumptive. The flesh of both the goat and kid is much esteemed in many countries, though of a peculiar flavour, arising probably from the aromatic shrubs and heaths on which the goat delights to browse. In Portugal and other countries the goat is used as a beast of draught. A notion of the wholesome influence imparted by the goat to the stable in which it may sleep, is very prevalent among the grooms of this country.

GO'BBING. In mining, the refuse thrown back into the excavations remaining after the removal of the coal.

GODROO'N. (Fr. godron.) In Architecture, an inverted fluting, beading, or cabling, used in various ornaments and members.

GO'DWIT. *See* LIMOSA.

GOG and MAGOG. The names of two warriors noticed in different portions of the sacred writings (Gen. x.; Ezekiel, xxxviii, &c.), and which since the Christian era have been regarded as nearly synonymous with Antichrist. The author of the Apocalypse (xx. 8.) uses the terms to express the nations hostile to Christianity; and Mohammed, in the Coran (21. 96.), employs them in a somewhat analogous sense. As is well known, the names Gog and Magog are given to the two huge warlike figures that adorn the Guildhall of London; but it is impossible to account for this singular application of the words.

GOITRE. *See* BRONCHOCELE.

GOLA, or GULA. (Lat.) In Architecture, the same as *Cyma*, which see.

GOLD. (Germ.) The most valuable and longest known of the metals. It sometimes occurs in regular veins in primary mountain districts; but the largest quantity is found in alluvial soils, and frequently in the beds and sands of rivers, as in Africa, South America, Mexico, Hungary, and Siberia. It is generally separated by washing away the lighter materials with which it is mixed, and subsequently by the process of *amalgamation*. Gold has been from the earliest period used as a measure of value and universal equivalent. For details on this subject, *see* MONEY.

Gold is characterised by its yellow colour; its extreme permanence in air and fire; its density, which is about 19·3; its malleability, which is such that it may be beaten into leaves not more than one two hundred and eighty thousandth of an inch in thickness; and its ductility, a grain of gold being drawn out into 500 feet of wire. Gold is not acted upon by the common acids; but chlorine and nitro-muriatic acid corrode and dissolve it, forming a chloride of gold, which is soluble in water.

The *alloys* of gold have been examined in detail by Mr. Hatchett. (*Phil. Trans.* 1803.) Of these the most important is that used for the gold coin of the realm, commonly called *standard gold*, which consists of eleven parts of pure gold and one of copper; it is extremely ductile and malleable, but harder than pure gold, and therefore better calculated to resist the wear and tear of circulation. The specific gravity of this alloy is 17·157: 20 lbs. troy of it are coined into 934 sovereigns and one half sovereign; 1 lb. troy, therefore, produces $46\frac{29}{40}$ sovereigns; the same weight was formerly coined into $44\frac{1}{2}$ guineas. The colour of this alloy is deeper yellow than that of pure gold, and verges upon orange: it frequently happens that a part of the alloy of gold coin is silver, hence the pale colour of some sovereigns as compared with others. Among the metals which destroy the colour and malleability of gold, none is so remarkable as lead. It appears from Mr. Hatchett's experiments that when lead forms about one two-thousandth part of the alloy, it is too brittle for rolling, and that the fumes of lead destroy the good qualities of gold. The chemical equivalent of gold is probably about 200, and that of the protoxide 208, and of the protochloride 236. The peroxide is a compound of one proportional of gold and three of oxygen, and the perchloride contains three proportionals of chlorine. When ether is agitated with solution of chloride of gold it takes up the metal, and forms a yellow ethereal solution of gold; when polished steel instruments are dipped into this solution, and immediately washed in water and wiped with a piece of soft leather, they become beautifully gilt with a very thin film of gold. *See* GILDING.

GOLDEN FLEECE. *See* ARGONAUTS. FLEECE, &c.

GO'LDEN NUMBER. *See* CYCLE.

GO'LDEN RULE. *See* RULE.

GO'LDFINCH. The common name of our well-known and brightest-plumaged songster; the *Carduelis elegans* of most modern ornithologists, *Fringilla carduelis* of Linnæus. This species feeds chiefly on the seed of the thistle and plantain; but builds its nest, which is of the neatest construction, in the fork of a branch of some densely-leafed tree, and lays four or five eggs, of a bluish white, spotted with brown at the greater end. The female is less brightly clad than the male, and the young have a comparatively simple plumage, in which brown predominates. In captivity the goldfinch is remarkable for its docility, and is prized for its beauty as well as its song. Hybrids are bred between the goldfinch and canary, and are much admired.

GOLF. A game with a ball and clubs, almost peculiar to Scotland, where it enjoys a degree of popularity equal to cricket in England.

GOLT. *See* GAULT.

GO'MARITES. In Ecclesiastical History, the Calvinist divines of the church of Holland in the 17th century were so called, from Francis Gomar, a colleague and opponent of Arminius at Leyden. *See* ARMINIANS. *Mosheim* (Trans.), ed. 1826, v. 325.)

GOMPHI'ASIS. (Gr. γομφος, *a nail.*) A disease of the teeth, when they loosen and fall out of the sockets. The grinding teeth are also called *gomphioi*.

GOMPHO'SIS. (Gr. γομφος.) A species of junction of bones where they are let into each other, something like pegs in a board.

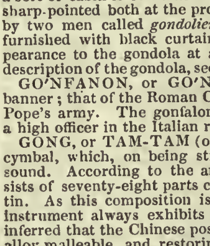
GO'NDOLA. (Ital.) The name given to the pleasure boats used at Venice, where the numerous canals with which it is intersected generally render it necessary to substitute boats for carriages. The gondola is from 25 to 30 feet long, and 5 feet wide in the centre, in which a sort of cabin is constructed for passengers. They are sharp-pointed both at the prow and stern, and are rowed by two men called *gondolieri*. The cabins are always furnished with black curtains, which give a sombre appearance to the gondola at a distance. For an accurate description of the gondola, see Lord Byron's *Beppo*, 19, 20.

GO'NFANON, or GO'NFALON. In Heraldry, a banner; that of the Roman Catholic church carried in the Pope's army. The gonfalonier or standard-bearer was a high officer in the Italian republics of the middle ages.

GONG, or TAM-TAM (of the Chinese). A species of cymbal, which, on being struck, produces a very loud sound. According to the analysis of Klaproth, it consists of seventy-eight parts copper and twenty-two parts tin. As this composition is extremely brittle, and the instrument always exhibits marks of the hammer, it is inferred that the Chinese possess the art of rendering the alloy malleable, and restoring it to its natural state of elasticity and brittleness when the instrument is formed. It is struck with a wooden mallet covered with leather.

GO'NIATITES. (Gr. γωνια, *an angle.*) A genus of extinct Cephalopods with chambered spiral shells; nearly allied to the *Ammonites*, but differing in having the lobes of the septa free from lateral crenatures or denticulations, so that the outline of these is continuous and uninterrupted. Goniatites are found in the mountain limestone of Yorkshire.

GONIO'METER. Gr. γωνια, *angle*, and μετρον, *measure*.) An instrument for measuring angles, and more particularly the angles formed by the faces of crystals. The instrument, chiefly used by mineralogists, was invented by Dr. Wollaston. It consists of a brass circle graduated on the edge, and furnished with a vernier, by which the divisions may be read correct to a minute. The circle moves in a vertical plane, and is supported on a stand. The axis of the circle is a hollow tube, within which is a smaller axis, fitting so tightly that when turned round it carries the other axis and consequently the wheel along with it, unless the latter is purposely prevented from moving. The interior axis is furnished with a milled head *a*, and the exterior with a milled head *b*;



so that when the head *a* is held and *b* turned the circle may be moved independently of the smaller axis, and when *b* is held and *a* turned the smaller axis may be

turned independently of the circle. Attached to the end of the smaller axis is a sort of universal joint, capable of being fixed in different positions by means of screws. The crystal to be examined is attached to the joint at *c* by a little soft wax, and placed so that its edge shall be parallel to the axis of motion; which adjustment is obtained by placing it so that the image of some horizontal object, as the bar of a window, successively reflected from the two faces of the crystal, coincides with another horizontal line seen by direct vision. When this adjustment has been made, the instrument is turned till the horizontal object is seen reflected from one of the faces. The smaller axis is then held fast, and the other turned till the index of the vernier points to the zero of the graduated limb. The circle is then turned round, along with the smaller axis, till the same object is seen in the same position by reflection from the other face of the crystal; when the arc passed through by the circle is obviously the supplement of the angle formed by the two faces of the crystal. In order, however, to avoid calculation, the supplements of the angles are marked on the limb, so that the angle to be measured is read off immediately.

Other forms of the goniometer have been proposed by Charles, Malus, and Brewster. (See Biot, *Traité de Physique*, tom. iii.; and *Brewster's Treatise on Philosophical Instruments*.)

GO'NOPLAX. (Gr. γωνια, *a knee*, and πλαξ, *a plate*.) A genus of crabs or short-tailed Crustaceans (*Brachyuri*), characterized by the angular square or rhomboidal form of their upper crustaceous plate or carapace, and by the length of the eye-stalks. One species (*Gonoplax rhomboides*) inhabits the Mediterranean, and is a good swimmer; but most of the rest of the genus are tropical.

GO'NYS. (Gr. γονυ.) In Ornithology, the inferior margin of the symphysis of the lower jaw, or the united anterior extremities of the guathidia.

GOOD FRIDAY. The name given in England to the anniversary of our Saviour's crucifixion. The French and most other European nations substitute the epithet *holy* for *good:* the Germans designate this day "Stiller-freitag," or "Char-freitag:" the latter appellation being derived from an old word, "charen," signifying *to do penance*, or *to suffer*. From the first dawn of Christianity Good Friday has been regarded as a solemn festival by the great body of the Christian world.

GOOD WILL. In Law, the custom of any trade or business. A contract to transfer it is, in general, good at law; though not usually enforced in equity. In what cases the good will of a partnership can be claimed as property by the representatives of a deceased partner appears doubtful.

GOOSE. *See* ANAS.

GOO'SEWINGS OF A SAIL. Half the sail loosed; the other half being kept furled, from the violence of the wind.

GO'RDIAN KNOT, in History, was a knot made by Gordius, king of Phrygia, in the harness of his chariot, so intricate as to baffle every effort to untie it. The oracle having declared that he who untied this knot should be the conqueror of the world, Alexander the Great, as is well known, made the attempt; but fearing lest in the event of his failure it should be considered as a bad omen, and interpose an obstacle to his future conquests, he cut it asunder with his sword; and thus, says Quintus Curtius, either fulfilled the oracle or eluded it. Aristobulus, however, gives a different version of the story. (See *Arrian*, book iii. c. 20.; and *Plutarch*, *in vit. Alex.*)

GORGE. (Fr.) In Fortification, the entrance into a bastion or other outwork. The *gorge* of a bastion is what remains of the sides of the polygon of a place after cutting off the curtains. The *gorge* of a ravelin, or demilune, is the space between the two ends of the faces next the place. The *demi-gorge* is that part of the polygon between the flank and the centre of the bastion. *See* FORTIFICATION.

GORGE. In Architecture, the same as *cavetto*, which see.

GO'RGET. (Fr. gorge, *a throat*.) In Plate-armour, the piece covering the neck attached to the helmet. The old covering for the neck was called *camail*, made of leather or cloth, and attached to the hood; on this plates of steel were riveted; and thus the gorget was formed, about the time of Edward II. The name is supposed to have originated in Lombardy.

GORGET. A surgical instrument used in the operation of lithotomy.

GORGONEI'A. (Gr.) In Architecture, carvings of masks imitating the Gorgon or Medusa's head.

GO'RGONS. In Mythology, three sister deities, fabled by the Greeks to dwell near the Western Ocean. Their heads, which were twined with serpents instead of hair, had the power of turning all who beheld them to stone; of which property Perseus made use after he had, by the help of Minerva, cut off the head of Medusa.

GO'SPEL, is used to signify the whole system of the Christian religion, and more particularly, as the term literally implies, the good news of the coming of the Messiah. The word was also originally applied to the books which contained an account of the life of Christ, many of which were in circulation in the first century of the Christian era; though only four, those of Matthew, Mark, Luke, and John, were considered canonical by the fathers.

GO'THIC ARCHITECTURE. *See* ARCHITECTURE, and ENGLISH ARCHITECTURE.

GOULA'RD'S EXTRACT OF LEAD. A subacetate of lead, obtained by boiling powdered litharge in vinegar.

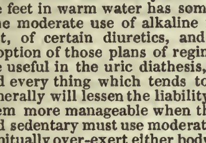
GOUT. The origin of this term, from the French *goute*, is obscure: it is a common disease among the higher classes of society, especially among those who indulge in the luxuries of the table, or inherit a disposition to its attack. Females are much less subject to it than males. Medical writers have distinguished several species of gout, and have called the disease in its ordinary form the *regular gout*. The first symptoms of its attack are those of dyspepsia and irregularity of bowels, low spirits, and some fever and restlessness; but these often pass unobserved till, the patient is roused in the night by violent pain in some part of the leg, generally in the vicinity of the great toe, and of one foot only: there is much throbbing and uneasiness, with more or less swelling and inflammation, and the least motion commonly produces great increase of suffering. After some hours the pain and fever abate, perspiration comes on; he falls asleep, and awakes comparatively easy. These fits or paroxysms are apt to return at intervals, and often every evening; but they decrease in violence, and at length go off, frequently with some decided increase of perspiration or other evacuation: the affected part itches, and the cuticle peels off, more or less lameness or uneasiness remaining. But the fit only thus leaves the patient for a time, and returns at intervals of longer or shorter duration, according to his habit of body and the care which he takes of himself; and the attacks not only become more frequent and severe, but last longer, and extend to other limbs; and when they have been frequently repeated, they leave a permanent stiffness of the joints, upon which *gouty concretions* are often deposited: and if much attention is not paid to the state of the urine, fits of sand and gravel not uncommonly precede or accompany those of gout. Where the disease is of long standing, and the form of it severe, the body becomes maimed and decrepit, and the mind often worn and irritable; the joints of the feet and hands, and even the larger joints of the extremities, are stiff and nearly immovable; and the formation of the chalky matter, as it is called, about the joints increases. If we consider the nature of this secretion in the joints, which is *urate of soda*, and the tendency of gouty persons to those morbid states of the kidneys and urine which depend upon excess of uric acid, and even upon the frequent alternation of fits of gravel with those of gout, the question will naturally suggest itself whether gout is not a symptom of what is often termed the *uric diathesis*, and whether the remedies applicable to it may not be beneficial in gout; and that in many cases they are so, seems to have been amply proved by experience. (*See* CALCULI.) It was once a favourite maxim that the gout was an effort of the system to relieve itself of some peccant matter; that, therefore, it was to be left almost to itself, and that patience and flannel were the chief remedies: this method still has its advocates, chiefly in consequence of the dangerous results that have sometimes attended more active plans of treatment in causing the revulsion of the gout from the limb to the stomach or head. But though there may be a difference of opinion in regard to certain energetic modes of relieving the disease, no one can object to the adoption of gentle means of quieting the urgency of the symptoms, and to the adoption of such diet and plan of living as appears to diminish the frequency of their recurrence. Warm laxatives, moderate diaphoretics and diuretics, and occasionally opiates, are among the former; and plain food or vegetable diet, with moderate exercise and tonics, are good preventives. Those, however, who have witnessed the sufferings of a regular paroxysm, and the evils of its duration and repetition, will see the necessity of doing something more; that is, of speedily quelling the pain and carrying off the attack, if it can be done with any chance of safety and success; and this experience shows to be often the case, though much care and judgment are undoubtedly requisite in conducting such treatment. In strong and healthy habits, the affusion of cold water is one of the most effective palliatives of the pain and inflammation; and by its timely application, *in proper cases*, the most beneficial results have ensued. Another celebrated remedy in this disease, and which by some has improperly been called a *specific*, is *colchicum*, or *meadow saffron*; — a due dose of which, taken at bed-time, has carried off the paroxysm; and this it often does without any remarkable evacuation, though it sometimes handles the patient severely as a purgative, and nauseates and

depresses to an alarming extent. This method of cure must not be unadvisedly and generally adopted; but in some cases, where gout had been long established, and where the frequency and duration of the fits and their inroads upon the constitution were increasing to an alarming extent, and that at an advanced period of life, colchicum, carefully administered, seems to have carried off the severity, if not the frequency of the attacks, and to have prolonged existence in consequence. But there are forms of gout, and consequences of gout, the management of which requires the utmost skill and experience: it is sometimes transferred or translated from the limbs to some internal part, in which case it is called *retrocedent gout;* or it produces sickness, dejection of spirits, fainting, palpitation, and giddiness, as in what is termed *atonic gout;* or it falls at once upon some internal part, especially the stomach, and is then called *misplaced gout.* In gout of the head and of the stomach the symptoms are often frightfully severe, and the pain excessive; and as these forms of gout are of most common occurrence in debilitated habits and broken constitutions, they become, on that account, the more difficult to treat: the expulsion of the disease to the extremities is in such cases sometimes effected by ether, brandy, or what are termed *gout cordials,* which generally consist of warm aperient tinctures; but before these are administered, it must be ascertained that the symptoms are really those of gout, and not idiopathic or common inflammatory actions. In such cases, putting the feet in warm water has sometimes been serviceable. The moderate use of alkaline remedies, of a vegetable diet, of certain diuretics, and generally speaking the adoption of those plans of regimen and medicine which are useful in the uric diathesis, are also useful in gout; and every thing which tends to repair the constitution generally will lessen the liability to its attacks, and render them more manageable when they occur. The indolent and sedentary must use moderate exercise, and those who habitually over-exert either body or mind must endeavour to tranquillize both: without such precautionary measures are most peremptorily enforced, no gouty person can expect much benefit from physic.

GOU'TY CONCRETIONS. These form in the joints of gouty persons, especially of the toes and fingers, and are sometimes, from their appearance, called *chalk stones;* they are composed of uric acid and soda.

GO'VERNMENT. In Politics, a word used in different senses: — 1. As the collective body of the fundamental laws of a state: as when the government of a country is said to be monarchical, aristocratical, &c. 2. The body of persons charged with the conduct of the executive in any country: thus, the king or presiding magistrate, the cabinet ministers, chiefs of departments, &c. in every country, form what is commonly styled its government.

GO'VERNOR. – A contrivance for regulating the speed of machinery, which has long been in use in mill-work, but has of late years attracted more attention by its adaptation to the steam engine. It consists of two heavy balls B B, attached to the extremities of two rods B F, B F, which play upon a joint at E, passing through a mortise in the vertical shaft D D. These



are united by joints at F to the short rods F H, which again are connected by joints at H to a ring which slides on the shaft D D. A horizontal wheel, W, is attached to D D, having a groove to receive a rope or strap on its rim, by means of which the motion is communicated to D D from a corresponding wheel on some shaft of the machinery to be regulated. It is evident, from the disposition of the rods, that if the balls B B are by any means raised or drawn asunder, the extremities F F of the rods turning on the pivot E will also be separated, and their distance from the axis increased. This will draw the rods F H in the same direction, and cause the ring or collar H to descend. This ring is connected with the end I of a lever, whose fulcrum is at G, and whose other extremity K is connected by some means with the part of the machine which supplies the power. Suppose now the velocity from any cause to undergo a sudden increase; by reason of the increased centrifugal force arising from the whirling motion, the balls B B will recede from the shaft D D, and raise the extremity K of the lever. On the other hand, if the velocity is diminished, the centrifugal force of the balls will be diminished, and they will fall by their own weight nearer the axis, and cause the end K of the lever to descend. When the governor is applied to a steam-engine, the rod K I communicates with a flat circular valve V, placed in the principal steam-pipe, and so arranged that when K is elevated as far as the divergence of the balls will allow, the opening of the pipe will be closed by the valve V, and the passage of steam entirely stopped. On the other hand, when the balls subside to their lowest position, the valve will be entirely open. Thus, when the velocity is increased, the supply of steam is checked; and when it is diminished, the supply of steam is immediately increased; by which means a uniform proper velocity of the machinery is maintained.

When the governor is applied to a water-wheel, the lever is made to act on the shuttle through which the water flows, and thereby controls its quantity. When applied to a wind-mill, it regulates the sail-cloth so as to diminish the efficacy of the power upon the arms as the force of the wind increases, or *vice versâ.* (*Lardner's Cyclopedia*, art. "Mechanics;" *Gregory's Mechanics*, vol. ii.) See also REGULATOR.

GO'VERNOR-GENERAL, THE, OF INDIA, is also the head of the local government of the presidency of Bengal. He exercises some of the most important rights of sovereignty; as, declaring war and making peace, framing treaties, and, to a certain extent, enacting laws. He has a council, consisting of five members; of whom three are servants of the Company; one appointed by the directors, but not a servant of the Company; and the fifth is the commander-in-chief. But the governor-general is independent of his council, except in a judicial capacity. If the council dissent, its members can record their reasons; such dissent, however, only operates as a suspensive veto on the decision of the governor-general for 48 hours. He has the commission of captain-general, and may head military operations in any part of India. He has also the power of suspending the governors of the other presidencies. But in his disputes with his own council or other governor, he is under the supervision of the Court of Directors and Board of Control at home. Regulations passed by the governor-general in council become immediately effective, but are subject to reversal by the home authorities.

GRACE (Lat. gratia), in the language of the New Testament, is primarily the favour and love of God towards any person: from thence it comes to be used in various derivative senses, being put generally for all the extraordinary means and assistances with which men are endowed to bring them to salvation, in all of which regard is had to the sacrifice of Christ as the ground upon which God vouchsafes them. The term is used, farther, for the good actions and dispositions of men, which may be supposed to be derived from the operation of the grace of God in the first instance.

The explanation of the term "grace" has given rise to some of the most remarkable controversies in ecclesiastical history. It is evident that it borders close upon the question of free will and necessity, and the discussion of the one is inextricably entangled in the difficulties that beset the other. The Pelagians, holding extreme opinions on the side of the freedom of the will, conceived the idea of grace operating from without, and controlling or in any way directing men's actions, to be subversive of their fundamental principle: they contrived, therefore, to understand the words of Scripture throughout of the *natural* good dispositions of men, whom they supposed to find favour in the sight of God by their own merit, and by their own voluntary acceptance of his promises to inherit eternal life. St. Augustin, on the contrary, maintained against them that the mere desire for grace is itself a special gift of God,—a free grace independent of and antecedent to any human actions, to the exclusion of any counteracting principle; a doctrine which, if rigidly interpreted, seems certainly irreconcilable with that degree of liberty which is a necessary element in the moral government of the world.

GRACE. In the Fine Arts, a quality arising from elegance of form and attitude combined. A figure may be just in its proportions, its parts and members may be all perfectly regulated, yet it may be deficient in grace. It is scarcely possible in words to express this quality, yet it is constantly seen in nature; and it is scarcely possible to contemplate a picture by Raffaelle without feeling its power.

GRACE AT MEALS, THE SAYING OF, is a Jewish custom, and appears to have been sanctioned by the practice of our Saviour. (Mark, viii. 6.; Matth. xiv. 19.) It is mentioned by Jerome and Tertullian as usual among the early Christians. A custom of beginning meals by prayers was common in classical antiquity. (*Livy*, xxxix. 43.; *Quintil. Declam.* 301.)

GRACE, DAYS OF, in Commercial Law, are certain days allowed by the custom of merchants to be added to the time requisite for presentment of a bill. Thus, if an instrument drawn in this country be payable "a certain time after date," three days of grace are added: a bill drawn on the 27th of August, payable "two months after date," is therefore due on the 30th of October. So if a foreign bill be drawn at one, two, or more "usances," the days of grace are added to the usance. The usance between London and Paris is one calendar month: a bill drawn in London on Paris, "at one usance," on the 2d January, is consequently due on the 5th February. The number of days of grace varies in different countries. In France none are allowed.

GRA'CES. (Gr. χαριτες; Lat. gratiæ.) In Mythology, the three sister goddesses, Euphrosyne, Aglala, and Thalia; attendants on Venus. The Graces, in Sculpture, were originally represented clothed; but in later times entirely naked. (*Hor. Od.* lib. iii.; *Pausan.* lib. ix.) In one of the groups of statues described by Pausanias they held respectively a rose, a die, and a leaf of myrtle. In the *Iliad* they appear as attendants of Juno; in the *Odyssey*, of Venus. Their temples were often dedicated also to Venus, to Cupid, the Muses, Mercury, or Apollo. (There is a dissertation on these goddesses by Massieu, *Acad. des Inscr.* vol. iii.)

GRACES. In Music, ornamental notes attached to principal ones, such as the appoggiatura, shake, &c.; which see.

GRACIO'SO. The buffoon; a favourite character on the Spanish stage. (See *Quart. Rev.* vols. lix. lxxviii.)

GRA'CULA. (Lat. graculus, *a jay*.) A genus of Dentirostral Passerine birds, characterized by a moderately long, slightly arched, and notched beak; nostrils situated anterior to the base of the beak, oblong, open, and notched; tongue with a short apex, often bifid. One species of this genus (*Gracula tristis*, Cuv.) is a native of India, and has been imported into the islands of Bourbon and the Mauritius, where it is held in the highest estimation for the services it performs in restraining the undue increase of locusts. The bird commonly called the mino grackle (*Gracula religiosa* of Linnæus) is the type of the genus *Eulabes* of Cuvier.

GRADA'TION. (Lat. gradus, *a step*.) In Painting, the gradual blending of one tint into another.

GRADA'TION. In Music, a diatonic ascending or descending succession of chords.

GRA'DATORY. (Lat. gradus.) A term applied in Mammalogy to the extremities of a quadruped which are equal, or nearly so, and adapted for ordinary progression on dry land. In Ornithology, the "pedes gradarii" are those in which the whole tibia is covered with feathers.

GRA'DIENTS. *See* RAILWAYS.

GRA'DUATE. (Lat. gradus.) One who has taken a degree in a college or university. *See* DEGREE, COLLEGE, UNIVERSITY.

GRADUATED. In Ornithology, when the quill-feathers of the tail increase in length by regular gradations.

GRADUA'TION. In Practical Astronomy, the division of circular arcs into degrees, minutes, &c. This is an art which, though depending on the geometrical properties of the circle, requires, to be successfully executed, the application of very great practical skill. For the principles, see Mascheroni, *Géométrie du Compas;* and for the practical part, *Troughton's Account of a Method of Dividing Astronomical and other Instruments, &c.*, in the *Phil. Trans.* 1809; also the article "Graduation" in *Brewster's Encyc.*, by the same eminent artist.

GRADUA'TOR. Contrivances for accelerating spontaneous evaporation by the exposure of large surfaces of liquids to a current of air have been termed graduators; and in some salt works, where the brine is strengthened by allowing a shower of it to trickle over faggots, the process is called *graduation*. Vinegar is sometimes manufactured by suffering a mixture of alcohol and water previously mixed with a little vinegar or some ferment to filter through a tub filled with beech shavings, through which a current of air is at the same time passing.

GRA'FTING. In Horticulture, the operation of affixing one portion of a plant to another in such a manner as that a vital union may take place between them. Grafting may be performed both with herbaceous and ligneous plants; but in practice it is chiefly confined to the latter, and more especially to the propagation of esteemed varieties of fruit trees. A grafted plant consists of two parts: the stock or stem, which is a rooted plant fixed in the ground; and the scion, sometimes, but erroneously, termed the graft, which is a detached portion of another plant to be affixed to it. The operation of grafting can only be performed within certain physiological limits; but what these are science has not yet absolutely determined.

In general, all the species of one genus may be grafted on one another reciprocally; but this is not universally the case, because the apple cannot be grafted on the pear, at least not for any useful purpose. In general, it may be presumed that all the species of a natural order, or at least of a tribe, may be grafted on one another; but this does not hold good universally. The reverse of this doctrine, however, viz. that the species belonging to different natural orders cannot be grafted on one another, holds almost universally true; and therefore a safe practical conclusion is, that in choosing a stock the nearer in affinity the species to which that stock belongs is to the scion the more certain will be the success.

Grafting is one of the most important operations in horticulture, as affording the most eligible means of multiplying and perpetuating all our best varieties of fruit trees, and many kinds of trees and shrubs not so conveniently propagated by other means. Varieties of fruits are originally procured by selection from plants raised from seed, but they can only be perpetuated by some mode which continues the individual; and though this may be done by cuttings and layers, yet by far the most eligible mode is by grafting, as it produces stronger plants in a shorter time than any other methods.

Grafting is performed in a great many different ways, but the most eligible for ordinary purposes is what is commonly called splice grafting, or whip grafting. In executing this mode both the scion and the stock are pared down in a slanting direction; afterwards applied together, and made fast with strands of bast matting, in the same manner as two pieces of rod are spliced together to form a whip handle. To insure success, it is essentially necessary that the alburnum or inner bark of the scion should coincide accurately with the inner bark of the stock; because the vital union is effected by the sap of the stock rising up through the soft wood of the scion. After the scion is tied to the stock, the graft is said to be made; and it only remains to cover the part tied with a mass of tempered clay, or any convenient composition that will exclude the air. The season for performing the operation is, for all deciduous trees and shrubs, the spring, immediately before the movement of the sap. The spring is also the most favourable season for evergreens; but the sap in this class of plants being more in motion during winter than that of deciduous plants, grafting, if thought necessary, might be performed at that season.

Grafting by approach, or inarching, is a mode of grafting, in which, to make sure of success, the scion is not separated from the parent plant till it has become united with the stock. For this purpose the stock and the plant containing the scion must be growing close together; and the scion being drawn to one side, and made to approach the stock, is spliced to it by cutting off a portion of its bark and wood, and a similar portion of the bark and wood of the stock, applying the one to the other so that their alburnums may join, and then making both fast by matting, and excluding the air by clay, grafting wax, or moss. When the scion has effected a vital union with the stock, its lower extremity is cut through, so as to separate it from the parent plant, and it now becomes an independent graft. In this way trees of difficult propagation may be propagated with certainty; while if any of the other modes of propagation, whether by cuttings or grafting, were adopted, a proportion of the cuttings or scions would, in all probability, be lost.

Grafting herbaceous plants differs in nothing from grafting such as are of a woody nature, excepting that the operation is performed when both stock and scion are in a state of vigorous growth. Grafting herbaceous plants is but little practised in England, and on the Continent chiefly as a matter of amusement. The only useful purpose to which it has hitherto been applied is that of grafting the finer kinds of dahlias on tubers of the more common and vigorous growing sorts. In the Paris gardens the tomato is sometimes grafted on the potato, the cauliflower on the borecole, and one gourd on another, as matter of curiosity.

Grafting the herbaceous shoots of woody plants—the greffe herbace of the French—is scarcely known among English gardeners; but it has been extensively employed by French nurserymen, and even in some of the royal forests of France. The scions are formed of the points of growing shoots; and the stocks are also the points of growing shoots cut or broken over an inch or two below the point, where the shoot is as brittle as asparagus. The operation is performed in the cleft manner; that is, by cutting the lower end of the scion in the form of a wedge, and inserting it in a cleft or slit made down the middle of the stock. The finer kinds of azalias, pines, and firs are propagated in this way in the French nurseries; and thousands of *Pinus laricio* have been so grafted on *Pinus sylvestres* in the forest of Fontainebleau. At Hopetoun House, near Edinburgh, this mode of grafting has been successfully practised with *Abies Smithiana*, the stock being the common spruce fir.

GRA'LLÆ. (Lat. grallæ, *stilts*.) The Linnæan name of the order of long-legged wading birds.

GRA'MINA'CEÆ. An order of Endogenous plants, commonly called grasses, in which the parts of fructification are essentially perfect, although they are in a very unusual state in what may be called their accessory organs. They have neither calyx nor corolla; but, in lieu of them, imbricated scales, called paleæ and glumes: the latter of which give rise to the name *glumaceous*, often applied to these plants. They are nearly allied to sedges, from which they differ in having the sheaths of their leaves slit and their stems hollow. Corn of all kinds, the bamboo, the sugar-cane, many kinds of pasture plants, and reeds, belong to different species of *Graminaceæ*. Ergot is the ovary of rye attacked by a fungus called *Ergotatia abortans*. The flinty surface of the stems or straw renders many valuable for domestic use, as for forming the *plat* from which straw bonnets, &c. are

manufactured. The systematical arrangement of grasses is a difficult and unsatisfactory task, and has occupied the attention of many botanists. The most recent work upon the subject is *Kunth's Agrostographia*, published at Berlin in 1836. *Sinclair's Hortus Gramineus Woburnensis* is a useful account of the relative qualities of pasture grasses.

GRAMMAR. (Gr. *γραμματικη τεχνη*, *the grammatical art;* from *γραφω*, *I write.*) The science which has for its object the laws which regulate human language. Language, in its widest acceptation, may be defined to be the expression, by means of outward signs, of what passes in the mind. If, therefore, it is to admit of rules, or general laws, it is plain that we must seek those laws either in the constitution of the mind where it originates, or of the outward materials of which it is composed. These are either sounds, visible images, or gestures. The first two of these, as admitting of the greatest variety, and capable of being most easily distinguished from each other, form by far the most considerable part of language, and that part alone which grammar takes account of. The material of language, when it is *sound*, is capable of analysis into a definite number of simple elements. It is not our object at present to enter on the consideration of this part of language, whether consisting of sound, or marks to designate sound. We pass on to its more important class of laws, which result from the internal conditions of the mind; and which, viewed in that reference, constitute the subject matter of philosophical grammar, properly so called. An analysis of our mental faculties must therefore precede any attempt to define the province and settle the principles of grammar. Of the various divisions of the human faculties proposed by philosophers, we shall adopt, as best suited to our purposes, that which distinguishes them into two grand classes, — the province of affection, and that of perception or intellection. The discriminating mark of the former class, under which we include alike the outward senses and the inner sense or emotion, is this, that the faculties which it includes imply a state of mind or consciousness, and that only. By perception or intellection, on the other hand, are meant those states of mind which refer to a real or supposed *object*, out of the mind itself. "To know" and "to know nothing" are contradictory conceptions; every act of knowledge implies at once an object and a mind to which that object is present. Each of these portions of the mind has its appropriate expression, its peculiar language. The language of emotion is common to men and animals. It consists, for the most part, of certain simple sounds or exclamations, which, if capable of being reduced to rules at all, must rest for those rules on physiological considerations, which form the province of philosophical grammar. We must seek that province, consequently, in the language of intelligence or reason. Rational discourse, or human language, may be figuratively expressed as the outward *type* or *form* which thoughts, and the laws which regulate them, impress on the *material* of sound. In the words of Plato, "reason and discourse are one; only the former, as the conversation of the soul with herself, which goes on without the intervention of sound, has obtained among us the name of discourse of reason." We do not deny that language, in this limited sense, may become the expression of emotion in ourselves, and excite emotion in others. Both these objects, however, it can effect only *mediately:* the first, by converting, through reflection, an emotion into an object of consciousness; by rendering it *intelligible* to ourselves, then *intelligible* to others: the second, only *through* the understanding of those whom we address. The laws of language must therefore correspond with the laws of the intellect: if there is any thing universal and necessary in the one, its representative or image must be found repeated in the other. But the necessary laws of thought are the object matter of logic. It might, therefore, seem that logic and universal grammar are convertible terms. Both sciences consider alike the forms of the intellect, and the right mode of expressing these forms in language. But they differ in this, that logic considers the intellectual process primarily, and its expression in language only incidentally; whereas grammar considers the former only in so far as it conduces to the right understanding and due regulation of the latter. Having previously distinguished philosophical from merely practical or empirical grammar, we may now distinguish philosophical grammar itself into universal and particular. The first, as we have seen, corresponds to logic: — as the one is the science of those conditions which must be presupposed in order to render *thought* and *intelligence* possible; so the other contemplates the conditions which are to render possible the *outward expression* of thought and intelligence. The same relation which universal grammar bears to logic, particular grammar, philosophically treated, may be said to hold to the kindred science of psychology. It considers the experimental laws of the mind with the same view with which universal grammar contemplates those that are necessary. It takes into the account the effects of accidental association, in order to explain the idioms or peculiarities of the particular language before it. It calculates, so to speak, the disturbing forces which act on the general law.

In developing the principles of universal grammar, we shall consider, in order, the various kinds of words or "parts of speech" into which language is ordinarily distinguished.

The first class of words corresponds to the faculty called by logicians apprehension, or simple apprehension. They are commonly named *nouns*, or *substantives*, or *nouns substantive;* and express either individuals, as "John, Charles;" or classes, as "man, animal." They are called substantives, because they express a real or supposed substance (Lat. *sub*, *stare*), a something which is conceived to stand under, or, in scholastic language, to be the support of, certain qualities. These qualities may in their turn be considered as substances, and expressed by substantives, as *whiteness*, *greenness*. When considered in relation to the substance of which they are properties, they constitute the second class of words, — *adjectives*, or *nouns adjective*. Thus we say "a *white* horse, a dazzling *whiteness;*" where the same conception which in the former case is regarded as a quality, and expressed by an adjective, is in the second converted into a substance, itself the *support* of other properties.

Thus far the only intellectual power implied in language is that of forming general conceptions. A conception, when formed, is capable of being resolved back into its constituent parts. In the conception "stag" we find the property of swiftness contained. This *attribution* of a quality to a substance is what logicians call a *judgment;* its expression in language is an *affirmation*, or *proposition*. The *sign* of this attribution is called the *copula:* "The stag *is* swift." Every judgment which has regard to matter of fact considers an event either as past, present, or future: "The hair *was* light, *is* dark, *will be* grey." When the attribute property or quality is combined with the copula or word signifying the affirmation or attribution, a third class of words is produced, to which we give the name of *verbs*. Thus instead of saying, "the sun *is* bright," we may say, "the sun shines;" where the latter form of expression is equivalent to, or capable of being analyzed into, the former. A *verb* is therefore a compound part of speech, consisting of an adjective and a *copula* or *affirmation*, and signifying not only the conception of a *property*, but our perception or judgment that such property does inhere or belong to some substance, or else that it *has* belonged or *will* belong to it. The relation between property and substance, expressed in every proposition, may be differently stated as the relation of part to whole, of species to genus, of individual to species; distinctions which do not concern us at present, inasmuch as grammar, no less than logic, has regard only to our mode of conceiving things, not to things as they are in themselves.

The three parts of speech which we have thus analyzed — the substantive, the adjective, and the verb — are called the *primary* or *essential* parts of speech. They are those without which no discourse could take place, no act of judgment be communicated; in other words, without which no sounds could have *meaning*. The parts of speech which remain to be considered are the *pronoun*, the *article*, the *adverb*, the *preposition*, the *conjunction*, the *interjection*.

The *pronoun* is so called from its being a substitute for a noun; a compendious contrivance to avoid repetition, or needless and inconvenient specification: as, "John is tall and *he* is handsome," which is equivalent to saying "John is tall and *John* is handsome." They are commonly subdivided into personal or substantive, adjective, demonstrative, relative, indefinite, and interrogative pronouns.

Articles are words joined to substantives, for the purpose of defining whether the substance or conception is to be understood in a general sense, or in particular relation to an individual. When the first is our intention, we use in English no article whatever: as, "*Man* is corrupt;" by which we mean that corruption is an attribute of the genus "man," and not of any particular individual to the exclusion of others. In Greek, however, the use of the article is frequently equivalent to the omission of it in English, as *ἡ ευσεβεια*, *piety*. If we used the article *a* or *an*, we should, in most instances, mean that some individual or other of the species was contemplated: "I saw *a* horse." When we use the definite article *the*, we mean to specify which individual of the species we have in view.

The *adverb* derives its existence from the difficulty of defining by one word the precise quality of a particular object. When we say a thing is "green," we may call up in the minds of our hearers the image of a very different shade of greenness from that which we are describing. If we say it is "*very* green," our language is more definite. An adverb may consequently be described as a *modifying* part

of speech, joined with adjectives or verbs to define more accurately the degree of the quality or circumstances of the action predicated. That it is not an essential part of language is evident from the circumstance that its place may be supplied either by a termination. as "green*ish*," for "rather green;" or by a periphrasis, as "he walks with speed," instead of "he walks rapidly."

Prepositions are those parts of speech which express relations between substances. and are consequently joined only with substantives; as, "*from* the city *to* the country." We shall consider them more at length when we come to treat of the inflections of words.

As prepositions express objective relations, so *conjunctions* may be said to represent those of a subjective nature; or those relations which we perceive to exist between the judgments of our own intellect, whether of mere succession, of inference, or the like. They are consequently used to connect propositions together; as, "John is wise, *therefore* he is good;" "John is wise *because* he is good," &c. They are to the syllogistic faculty, or the faculty which perceives the connection and dependence of simple judgments, what the *copula* is to the faculty which forms these judgments. As the one forms words into propositions, so the other are necessary to combine propositions into sentences.

The *interjection* is the expression of emotions, and emotions only. It is not, therefore, confined to *human* discourse; and as it has nothing to do with the operations of the intellect, is incapable of logical combination with other words. It might therefore be doubted whether it can with propriety be called a part of speech or not.

We have said that the last-mentioned "parts of speech" were not *necessary* constituents of language. We so far qualify that assertion, in regard to prepositions in particular, as to admit that they are the expressions and modes of conception which the human understanding unavoidably forms. Whether, in technical language, the necessity be a *formal* or a *material* necessity, we forbear to discuss at large; since it is a subject on which logicians are not agreed. We ourselves are inclined, with Kant, to think it *formal*. We conceive the relations of cause and effect, of time and place, of action and passion, to be as much pure educt of the understanding, and as independent for their *form* on experience, as those of *part* and *whole*, *substance* and *attribute*, which we have seen to constitute the necessity for the primary parts of speech. They differ, however, in this, that the latter *must* enter into every proposition to render it a proposition at all; while those we are now considering may or may not, according to the matter in hand. In all languages they are expressed more or less perfectly. In our own, and in the other branches of the Teutonic stock, this expression is effected in two ways. Either the relation intended to be implied is expressed by an affix or prefix to the radical or abstract portion of the word itself; or the relation is regarded as abstracted from all particular objects between which it might be conceived to subsist, and, so abstracted, is embodied in a distinct word or particle. Thus what the Latins expressed by the termination *o* or *i*, as "domin*o*," "nub*i*," is represented in English by the prepositions "to" or "for." Generally speaking, the earlier a language the richer it is found to be in terminations; which, as the faculty of abstraction becomes habitual, are commonly abridged in number, and replaced by particles. A word which admits a variety of such modifications is said to be *declinable*. The only *declinable* or *inflected* parts of speech are the substantive and the verb, and in some languages the adjective and participle, with the representative parts of speech, the pronoun and article. The reason of this is sufficiently obvious. It is between supposed *substances* that the relations of cause and effect and those of place are conceived to exist; while the relations of *time* pertain to action and passion, or those changes in the state of substances which are expressed in language by verbs. The declension of adjectives is an anomaly in language. It probably results from the facility with which we convert in our thoughts a quality or attribute into a substance: unless it is to be accounted for by what grammarians call "attraction;" a supposed influence which the inflexion of a word exerts over those immediately in contact with it, and which is owing partly perhaps to the desire of euphony, and partly to a confusion of thought, the effect of association. The sum total of the modifications which the words of a language admit constitute what is called the *accidence* of that language. The circumstances under which such modifications or inflexions take place are the subject-matter of that part of grammar which is named *syntax*. These inflexions are, in *nouns*, case, number, and gender; in *verbs*, tense, mood, person, and, in most languages, number.

The *cases* of nouns are the expression of the relations of substances. In Latin there are, besides the nominative, or absolute form of a conception, and the vocative, used in addressing or calling to another person (a compound of a noun and an interjection), four cases properly so called; the genitive, the dative, the accusative, and the ablative. Of these the English language retains in its nouns one only, the genitive; in its pronouns two, the genitive and accusative. All other cases it replaces by prepositions.

The genitive case expresses the relation of *property*. A single conception is capable of being analyzed into a number of constituent parts, which are either necessary to the whole conception, or bound up with it by association more or less habitual. We represent this process in language by some change either in the word which signifies the *property*, or in that which denotes the containing substance. The last is the case in most European languages. Thus, we speak of a "horse'*s* colour," of "Socrates' philosophy."

The dative case implies *participation* in the effect of an action, expressed in English by the preposition "to" or "for." "Dedi ei,"—"I gave it *to him*;" where the effect of my act of giving is *shared only* by another.

The accusative is used where the effect of an action is conceived as passing over *entire* to another substance: "Laceravi librum,"—"*I tore the book*;" where the whole of the immediate effect is conceived as confined to the book which I tear. It is also called the objective case.

The ablative case, if we regard its etymology only, we should define to be that which expresses loss or privation. In this sense it ought to be considered as a modification of the dative, or the case which expresses the incidental or participated effects of an action; and we accordingly find that in Latin the English preposition "from" is frequently expressed by the dative. There is, however, a kind of relation which no other case serves precisely to convey, that of outward proximity. which is expressed in English by such prepositions as *at*, *near*, *by*, *upon*, and in Latin by the ablative case, which consequently is not so useless or superfluous a form as some grammarians have considered it to be.

Besides the inflexion of case, nouns admit, in most languages, those of number and gender. The latter is a mere generalization from experience; and though it may be convenient to have a termination to designate it, it is not necessary, as is apparent from our own language, which expresses this distinction only in its pronouns, and in some few of its substantives. Our conceptions of number are doubtless conditions of our mental constitution. They may be generalized under the forms of unity simple, unity comprehensive, and plurality. Unity, whether regarded simply or as an aggregate, is expressed by the singular number. Many languages, besides singular and plural, have a form to denote duality, or *two things together*; a fact which, probably, is owing to the duality of the parts of the human body, as the hands, feet, &c.

We proceed to consider the different kinds of *verbs*, and their modifications. Verbs are divided into transitive, intransitive, and passive. They admit necessarily of time and mood; accidentally and by usage of *person* and *number*.

A property, taking the word in the most general sense of which it is capable, may be conceived either as a state, a process, or as a power in action. To the first two correspond the verbs commonly called intransitive, or neuter, as "I rest," "I grow," "I fall." When a power is in action, we measure it by its effects on some substance; we conceive the action as *passing on* to another object, as "the clouds bring rain." The verb which expresses this transition is called the verb active or transitive. But not only are we able to conceive an object exerting power; we may also consider it as susceptible of influence or change from the action of another object. This is expressed by the verb passive, as "the dog *was beaten*." Many other modifications of action and change have their appropriate forms in different languages. Such are the verb middle or reflex in Greek, the verbs frequentative and desiderative in Greek and Latin. These, however, are matters of idiom, not of universal necessity.

Equally extensive with the conceptions of cause and effect is that of time, as the universal condition of all change in nature. The words which signify the one must therefore be capable of expressing the other. Hence the necessity for *tenses* in verbs, or the inflexions which determine the time of the action, as present, past, or future. We may further abstract an action from its relation to time altogether; and this abstraction is in some languages, as in the Greek, represented by a form appropriate to the purpose, called the aorist.

The modifications of verbs which we have been considering concern change or action objectively, or in relation to the substances which they are supposed to affect. Our judgments themselves are also liable to certain modifications, which, as regarding only the way in which we conceive of events, may be said to constitute the subjunctive conditions of verbs. Our knowlege of an occurrence may be either certain or uncertain; and uncertain either absolutely, or only under particular suppositions. When we simply express our judgment that a thing is, has been, or will be, in such and such a state,

we are said to speak indicatively, or in the *indicative mood*. When we consider a thing as possible merely, we use the *potential mood*, denoted in English by the auxiliary verbs "may" or "might." When we speak of it as dependent for its occurrence on certain conditions, or in case of its occurrence as connected with certain probable or inevitable consequences, we use the *conjunctive mood:* "I *would* go, if he *would* let me." Different languages express these modifications of judgment more or less perfectly; none, perhaps, with absolute accuracy.

Two other modal forms still remain to be considered. They have been called by grammarians the *imperative* and *optative moods*, as conveying the expression of a command or a wish. They may be included under the general term of desiderative, and imply at once the conception of an event and our desire that that event should take place. They may therefore be regarded as forming the connecting link between verbs and interjections; between the words which belong to the perceptive and those which pertain to the emotive part of our nature.

What is commonly named the *infinitive mood* may be considered as the point of transition from a verb to a substantive. It is, so to speak, a *substantized attribute*, and is used as the subject of a proposition as correctly as substantives themselves: *e.g.* "*To die* is gain."

The *participle* is usually ranked as a separate part of speech. It may be said to hold the same intermediate place between a verb and an adjective, as the infinitive holds between a verb and a substantive. It possesses all the properties of the verb, save affirmation; that is to say, to the properties of the adjective it adds the power of denoting time.

The attribution to verbs of number and person is logically as anomalous as it is to assign gender and number to adjectives. Most languages fall into this error, which is, however, susceptible of a very easy historical solution. It arose, doubtless, from the original custom of annexing the pronoun to the termination of the verb, and continuing the use of the inflection after its import had been forgotten, and when the pronoun had been formed into an independent part of speech.

Those who wish to investigate the principles of grammar more closely, would do well to consult Mr. Harris's *Hermes*, perhaps the most complete philosophical treatise on grammar that has appeared in England. See also the article "Grammar," in the *Encyclopædia Metropolitana*, where the paradoxical opinions of Mr. Horne Tooke on this subject are ably confuted. Professor Thiersch, in his *Greek Grammar*, some time since translated into English, has interspersed some ingenious and valuable inquiries into the general principles of language, from which the student may derive many important hints.

GRAMMA'RIAN. Literally one versed in grammar; but the term was used by the classic ancients as a title of honourable distinction for all who were considered learned in any art or faculty whatever. (See Vossius's work on Grammar.)

GRANA'DE. *See* GRENADE.

GRA'NARY. (Lat. granum, *corn.*) A building in which to lay or store corn, especially that designed to be kept a considerable time. Various scientific principles have been laid down for the erection of buildings of this nature, of which the reader will find a full account in *Rees's Cyclopædia;* but the most curious, as well as most efficient contrivances for housing and keeping grain in good order, are to be met with in some parts of Sicily. They consist either of excavations into calcareous rocks, or holes in the ground shaped like a bottle, walled up, and rendered waterproof by the neck of the bottle being hermetically closed with a stone fastened with gypsum. They contain about 200 salme, or about 1600 English bushels of corn, which may be thus preserved for an indefinite period; at least it has been found in perfectly good condition after the lapse of a century. (*Simond*, p. 25.; *Swinburne*, vol. ii. p. 405.)

GRAND. (Fr.) In the Fine Arts, a quality by which the highest degree of majesty and dignity is imparted to a work of art. Its source is in form freed from ordinary and common bounds, and to be duly felt requires an investigation of the different qualities by which great and extraordinary objects produce impression on the mind.

GRANDE'E. (Span. grande; from *grande de España.*) The highest title of Spanish nobility. The collective body of the higher nobility in Spain is termed *la grandeza*. They were originally the same with the *ricos hombres*. Grandees bear different titles — duke, marquis, &c.; but there is no essential difference of rank between these titles: all are equal among themselves. Grandeeships descend through females, and thus become accumulated in families. (*Quart. Rev.*, 1838.)

GRAND JURY. *See* JURY.

GRANGE. A farm-yard or farmery, which consists of a farm-house, and a court of offices for the different animals and implements used in farming, and also of barns, feeding houses, poultry houses, &c. *See* FARM-YARD, or FARMERY.

GRA'NITE. A crystalline aggregate of quartz, felspar, and mica, with the occasional addition of other minerals. It is regarded by modern geologists as of igneous origin, and as having been protruded from below, so as to elevate and dislocate the adjacent strata, and occasionally to penetrate them in the form of veins. Granite is a hard and generally durable rock, and of vast importance as a building material, and in its applications to pavements. The crystals of felspar are sometimes very large and distinct, and constitute the whitish imbedded masses which are seen in such perfection in some of the granite pavements of London, especially of London and Waterloo Bridges. When the mica prevails in granite, its texture becomes lamellar, and it passes into the rock which has been called *gneiss;* which again, by the gradual secession of the felspar, degenerates into *mica-slate*. There are some kinds of granite which are undergoing rapid disintegration and decay, in consequence of the joint action of air and water upon the felspar; the potash of which appears to be removed, and the residue falls into a white powder, composed chiefly of silica and alumina in a state of very fine division: it is thus that the celebrated *Cornish clay* is produced, which is in such request for the purposes of pottery. The curious district in which the Carglaise tin mine, near St. Austle, is situate, is a good and characteristic specimen of decomposing granite. *See* GEOLOGY.

GRANI'VORÆ. (Lat. granum, *a grain;* voro, *I eat.*) The name given by Temminck to an order of birds, including the Insessorial species, which feed on grains: other animals with a similar diet are termed "granivorous."

GRANT. In Law, a mode of conveyance by deed, appropriate to estates in lands and tenements not in possession, and also to incorporeal hereditaments.

GRA'NULATE. (Lat. grana, *a grain.*) When a surface is beset with many very small elevations like shagreen.

GRA'NULATION. The method of dividing metallic substances into grains or drops. It is usually effected by pouring the melted metal into water; and if fine division is required, it must pass through a perforated ladle or sieve; and in order to obtain spherical particles, it must fall from such a height as to have become solid before it meets with the water: hence the height of the towers in which *shot* is made.

GRA'NULATIONS. This term is applied to the little granular formations which arise in sores that are healing, and by which the destroyed parts are filled up and the edges brought together. When healthy they are of a red colour, not exuberant; when unhealthy they are pallid, and become soft, spungy, and irregular.

GRAPE-SHOT. In Artillery, a quantity of small shot put into a canvas bag, and corded together in the form of a cylinder, the diameter of which is adapted to the piece of ordnance from which it is intended to be discharged. It is now superseded by *canister-shot*.

GRAPHO'METER. (Gr. γραφω, *I write*, and μετρον, *measure.*) A mathematical instrument used in land surveying; otherwise called a *semicircle*.

GRA'PHITE. (Gr. γραφω.) The substance improperly called *black lead*, of which pencils are made. It is a peculiar form of mineral carbon with a trace of iron. The finest is found only at Borrodale in Cumberland. Coarser varieties are not uncommon.

GRA'PNEL. A small anchor for a boat.

GRA'PPLING IRONS. Small grapnels with four flukes for securing ships together in action.

GRA'PTOLITES. (Gr. γραφω, *I write;* λιθος, *a stone.*) A genus of fossil Zoophites, nearly allied to the existing sea-pens (*Pennatulæ*) found in the bituminous shales of the silurian sandstone deposits.

GRASSHOPPER. *See* LOCUST.

GRASS LAND. In Agriculture, land kept perpetually under grass, as contrasted with land which is alternately under grass and tillage. Perpetual grass lands are generally such as from the soil and situation are too moist to be ploughed with advantage, or too hilly and irregular on the surface to be ploughed at all. Hence we have hill pastures, and low moist meadows. The former admit of very little improvement, excepting that of drainage, and occasionally, in low hills, of irrigation; while the latter may not only be drained, but may be manured, and in some cases irrigated. *See* PASTURE, MEADOW, and IRRIGATION.

GRATE, may be described as the iron frame and bars for holding the fuel burnt in our fireplaces. It is, however, confined to the use of coal; wood fires being better kept up on what are called "dogs."

GRAU'WACKE. A German miner's term, implying *grey rock;* adopted in Geology to designate some of the lowest secondary strata, which form the chief part of the *transition rocks* of some geologists. *See* GEOLOGY.

GRAVE. In Music. *See* ALLEGRO.

GRA'VEL. A term applied to a well-known material of small stones, which vary in size from a small pea to a walnut, or something larger. It is often intermixed with other substances, such as sand, clay, loam, flints, pebbles, iron ores, &c., from each of which it derives a distinctive appellation. *See* GEOLOGY.

GRA'VEL. In Gardening, gravel is an important article, being that of which walks are formed whenever it can be procured. In selecting gravel two qualities are chiefly to be sought for; viz. a fine colour, and the property of binding. The most common colour of pit gravel is a rusty brown; and that of river or sea gravel a gray, with different shades of white, red, or brown. The best colour is considered to be a deep rich yellow, which is that of the gravel of Kensington, the stony parts of which are flints, — supposed to be the finest in the world, and which used formerly to be shipped, not only to different sea-ports of Great Britain and Ireland, but to various places on the Continent, to Petersburgh, to India. and even to South America. The binding properties of gravel are two: the presence of ferruginous clay of the same rich colour as the gravel, and which causes the gravel to set or become hard as soon as it is exposed to the action of the atmosphere; and the irregular and angular shapes and sizes of the stones. Where the stones are round or oval, with regular smooth surfaces, they never form a good binding gravel, even if they should be mixed with ferruginous clay. The reason is, that those stones which are on the surface, having no mechanical hold on those which are beneath or beside them, but being merely slightly cemented by means of ferruginous clay, are easily loosened and thrown out of their places by the action of frost, or even by the alternate action of drought and moisture. Hence, where no other gravel but that found in rivers or on the sea shore can be found for making garden walks, one half of the stones ought to be broken and mixed with the other half before laying them on the walks. The Kensington gravel, applying that term to all those of a similar colour and quality in England, binds better than any other, not only on account of the ferruginous clayey matter with which it is mixed becoming hardened by the atmosphere, but also because the stones are exceedingly irregular in size and shape.

GRAVEL, URINARY. *See* CALCULUS and ELRINE.

GRA'VER, called also BURIN. The sharp tool, whose extremity is of a triangular form, for cutting the lines of an engraving on the copper. *See* ENGRAVING.

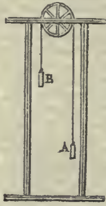
GRAVI'METER. (Lat. gravis, *heavy*, and Gr. μετρον, *measure*.) An instrument for ascertaining the specific gravities of bodies, whether liquid or solid. The particular instrument to which the term is usually appropriated was invented by M. Guyton; who adopted this name in preference to *areometer* or *hydrometer*, because these latter terms imply that the liquid is the thing weighed; whereas, when solids are weighed, the liquid is only the term of comparison to which the unknown weight is referred. *See* HYDROMETER.

GRAVITA'TION, GRAVITY. (Lat. gravis, *heavy*.) These terms are often used synonymously to denote that mutual tendency which all the bodies of nature have to approach each other, with forces which are directly as their masses and inversely proportional to the squares of their distances.

That every particle of matter in the universe has a disposition to press towards, and if not opposed to approach to every other, is a fact of which we derive the knowledge partly from our constant experience of what takes place at the earth's surface, and partly by reasoning from the observed motions of the celestial bodies. This mutual tendency of all the particles of matter to each other is called the *attraction of gravitation*. In reference to any particular body, or mass of matter, the aggregate attraction of all its particles is usually called simply its *gravity*.

Of Terrestrial Gravity.—Universal experience demonstrates that all heavy bodies, when unsupported, fall towards the surface of the earth. The direction of their motion may be ascertained by a plumb-line; and it is found to be always perpendicular to the level surface of the earth, that is, to the surface of stagnant water. But the earth is very nearly spherical, and a line perpendicular to the surface of a sphere must pass through its centre; hence the direction of a body moving in consequence of the force of terrestrial gravity is towards the centre of the earth. And this is the direction in which it must move if the force of gravity is the resultant of the attraction of all the particles of terrestrial matter on the falling body; for it has been demonstrated (by Newton) that a sphere attracts an exterior body in the same manner as if all its matter were condensed into a single point at its centre.

As bodies when left without support fall from all heights to which they may be carried, it may be inferred that gravity acts on them during the whole time of their descent, and is therefore a uniformly accelerating force. This might also be inferred from the fact, which is easily rendered sensible, that bodies which fall from a greater height arrive at the earth with a greater velocity. But Galileo was the first who proved by experiment that the acceleration of falling bodies is uniform, and that the spaces descended through are consequently as the squares of the times of descent. Experiments of this kind are attended with some difficulty on account of the resistance of the air. In order to render this resistance insensible, Galileo caused bodies to descend on planes having a small inclination to the horizon, in which case (neglecting the effects of friction) the velocity is diminished in the ratio of the sine of the plane's inclination. By mounting the descending body on wheels, and forming the inclined plane of a hard substance capable of receiving a perfect polish, the friction may also be so much diminished as not to change the nature of the motion. But the best method of showing experimentally that gravity is a uniformly accelerating force is by means of an apparatus called (from its inventor) Attwood's machine.



This consists of a pulley, the axle of which turns on friction rollers, and having a groove on its edge to receive a string. Over the wheel a fine silken cord is stretched, to the ends of which are attached two equal weights, A and B. In this state the weights counterbalance each other, and no motion ensues; but if to one of the weights a small load m be added, so as to give it a preponderance, the loaded weight will immediately begin to descend. The motion which now takes place is exactly of the same kind with that of a body descending freely; but the velocity is diminished in the proportion of the additional load m to the sum of the three, m, A, and B; for the force, which is impressed by the additional weight, is expended in giving velocity not only to it, but also to the two weights A and B attached to the string. By this machine the properties of uniformly accelerated motion are experimentally shown to hold true in the descent of falling bodies; for if the additional load be such as will carry the weight to which it is added through 1 foot in the first second of time, it carries it through 4 feet in 2 seconds, through 9 in 3 seconds, and so on. A proof is therefore afforded by this means that terrestrial gravity is a uniformly accelerating force.

Terrestrial gravity acts equally on all bodies; that is to say, impresses on all of them an equal quantity of motion, whatever their nature may be. This property of gravity was also demonstrated by Galileo. In different hollow spheres, of equal weight and diameter, he enclosed equal weights of different substances: the spheres were suspended by strings of equal length, and made to vibrate in very small arcs, and it was found that the time of an oscillation was the same in all of them. Common experience would seem to be at variance with this result. Light bodies, as feathers, paper, &c., fall slowly and irregularly; and some substances, as smoke, vapours, &c., even ascend. But this, as is well known, arises from the buoyancy of the atmosphere. In the exhausted receiver of an air-pump a piece of gold and a feather fall with the same speed, and strike the bottom at the same time.

Measure of Terrestrial Gravity. — Having ascertained the law according to which gravity acts on bodies at the surface of the earth, the next question is to determine its absolute intensity, or the velocity which it communicates to a body falling freely in a given time. On account of the rapidity of the descent of heavy bodies, this cannot be done by direct experiment; nor could Attwood's machine be employed for the purpose with sufficient certainty. The only mode by which an accurate result can be obtained is by measuring the length of a pendulum which makes a given number of oscillations in a given time. Let l be the length of the seconds' pendulum, π the ratio of the circumference to the diameter, and g the accelerating force of gravity, that is, twice the space through which a body falls by the action of gravity in the first second of time; then (PENDULUM) we have the equation $g = l\pi^2$. Now the length of the pendulum vibrating seconds of mean solar time in London, in vacuo, and reduced to the level of the sea, has been determined to be 39·1393 British standard inches; and $\pi = 3{\cdot}14159$; therefore g is found $= 386{\cdot}3$ inches, or $32\frac{1}{5}$ feet. The height, therefore, through which a body would fall in vacuo in a second of time at London is half of this quantity, or $16\frac{1}{10}$ feet. It will be observed, however, that this value of g does not express the whole of the earth's attraction, a small part of which (about the 1-464th) is counteracted by the centrifugal force corresponding to the latitude: it is the force of gravity diminished by the centrifugal force, or what is properly called *gravitation*.

From experiments made with the greatest care, it appears that the extreme amount of the variation of the gravitating force between the equator and the poles is one part in 194 of the whole quantity; that is to say, any body which at the equator weighs 194 pounds, if transported to the pole would weigh 195 pounds. The difference of gravitation, therefore, at the equator and the poles, is expressed by the fraction $\frac{1}{194}$. Now it has been demonstrated by Newton that the ratio of the centrifugal force at the equator to gravitation there is $\frac{1}{289}$. This is

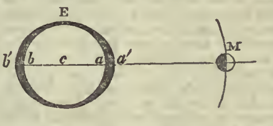
considerably smaller than the fraction $\frac{1}{194}$; but the difference, which is $\frac{1}{590}$, arises from the oblate figure of the earth, in consequence of which a body placed at the pole is at a less distance from the centre than one at the equator, and is therefore attracted more than it would be at the equator, even if the earth stood still, and there was consequently no centrifugal force. From this it may be readily understood that the figure of the earth is determinable by measuring the intensity of gravitation under different latitudes. *See* DEGREE, EARTH.

Universal Gravitation.—Galileo, who had so fully succeeded in exploring the nature of terrestrial gravity, did not suppose that its action extended to bodies beyond the immediate vicinity of the earth. The more speculative genius of Kepler led him to speak of gravity as a force acting mutually from planet to planet, and particularly from the earth to the moon; and he even supposed the tides to be produced by the gravitation of the waters of the sea towards the moon. He did not, however, suppose it to have any concern in the regulation of the celestial motions. Hooke also supposed the heavenly bodies to have a gravitation to each other; but his notions respecting its nature were inaccurate, and he did not attempt to define the law of its variation. This great discovery was reserved for Newton. While meditating on the nature of this force, the thought occurred to him that since gravity is a tendency not confined to bodies on the very surface of the earth, but reaches even to the summits of the loftiest mountains without its intensity or direction suffering any sensible change, may it not reach to a much greater distance, and even to the moon? Before this question, however, could be answered, it was necessary to suppose a law according to which its intensity diminishes. Newton soon perceived that this law would require the force of gravity to diminish exactly as the square of the distance increases; or that the attractive force of the earth at the distance of the moon must be as much less than it is at the surface of the earth, as the square of the radius of the earth is less than the square of the moon's distance from the earth. In a general way, the hypothesis is easily verified. The moon's orbit differs not much from a circle whose radius is equal to 60 times the semidiameter of the earth, and the circumference of her orbit is therefore about 60 times the circumference of a great circle of the earth. Now the diameter of the earth being nearly 8000 miles, and the period of the moon's revolution being 27 d. 7 h. 43 m., it is easy to compute that the versed sine of the arc described by the moon in a minute (which is the same as her deflexion from the tangent or straight line she would describe if there were no force attracting her to the earth) is $16\frac{1}{10}$ feet. But the mean distance of the moon from the earth being 60 times the distance of heavy bodies at its surface from its centre, and her gravity increasing in proportion to the square of the distance, her gravity would be 60×60 times greater at the surface of the earth than at her present mean distance, and therefore would carry her through $60 \times 60 \times 16{\cdot}1$ feet in a minute near the surface. But by what was proved by Galileo respecting the descent of heavy bodies, the same force would carry her through 60×60 times less space in a second than in a minute; and therefore the same force which compels the moon to move in her orbit about the earth, supposed to vary according to the inverse square of the distance, would cause her to fall, near the surface of the earth, through 16·1 feet in a second. Now this is exactly the space through which heavy bodies descend in a second; therefore the moon *may* be retained in her orbit by the power of terrestrial gravity.

Newton, however, did not allow the argument for universal gravitation to rest on loose considerations of the lunar orbit as a circle described with an average velocity about the earth. He demonstrated that bodies moving under the influence of an attractive force which diminishes according to the inverse square of the distance must describe conic sections having a focus at the centre of force, and observe the laws of motion which Kepler had discovered to belong to the planetary orbits. He succeeded also in proving that some of the principal inequalities of the lunar and planetary orbits are necessary consequences of the mutual gravitation of the different bodies of the system to each other; and that the same mysterious power not only regulates the motions of all the planets and satellites in space, but also determines the figure of the earth, causes the precession of the equinoxes, and produces the tides of the ocean.

Assuming the different bodies which compose the solar system to be acted upon by their mutual gravitation, according to the law proposed by Newton, namely, that each body attracts every other with a force proportional to its mass directly and to the square of the distance inversely, the determination of the motions of the several planets and satellites becomes a question of pure geometry when the requisite data are determined by observation. If, however, the problem were required to be solved in its most general terms, and it were necessary to consider simultaneously the effects of all the bodies in the system, the difficulties of calculation would be enormous, and in fact no methods of analysis hitherto discovered would be sufficient to grapple with them. Fortunately the actual condition of the system is such as to afford great simplifications. The principal planets are isolated in space, at great distances from each other, and their masses are very small in comparison of that of the central body; so that the effects of their mutual attractions are not such as to alter the general elliptic form of their orbits, but merely produce small *perturbations* of their orbits and motions, which admit of being separately computed. By availing themselves of these favourable conditions, mathematicians have succeeded in expressing the whole of the complicated movements of the planets and satellites by analytical equations; and such is the perfection to which this branch of physical science has attained, that there is now no irregularity in the motions of the bodies of the solar system, no deviation from their mean state appreciable to the most delicate astronomical observations, which has not been explained, and its period and amount accurately calculated on the principle of universal gravitation, according to the law discovered by Newton. *See* PLANET.

The effects of gravitation, as manifested in the influences of the celestial bodies on each other, enable us to form several conclusions respecting its nature and mode of action. That gravity belongs not only to matter in the aggregate, but to every particle of which bodies are composed, is rendered evident by the manner in which the moon disturbs the waters of the ocean. Let E be the earth, and M the moon. If the moon's gravity acted only on the aggregate mass and not on each particle, it would have no effect on the figure of the earth, and consequently no tide would be produced. But the action of the moon on the different parts is unequal.



Those at a, which are nearest the moon, are more attracted than those at the centre c; which again are more attracted than the parts at b, which are farthest from the moon. The consequence is, that a fluid particle at a is drawn away as it were from the general mass, and an accumulation takes place at a'. For the same reason, the attraction at c being stronger than at b, the mass of the earth is drawn away from the parts at b, and the fluid is in a manner left behind, and accumulates at b'. Hence we perceive the reason why it is high water on opposite sides of the earth at the same instant of time. In fact, in consequence of the moon's attraction, the fluids on the surface of the earth have a tendency at every instant to arrange themselves in the form of an elongated spheroid, the greater axis of which points towards the moon.

It is also proved by astronomical phenomena that gravity is a force which is transmitted from body to body, not successively, but instantaneously. Were gravity transmitted with a measurable velocity, the *rate* of velocity would sensibly affect the secular variation of the mean motion of the moon. By a comparison of the results of theory with observation, Laplace found that the velocity of the attracting force, if not infinite, must be at least *fifty millions* of times greater than the velocity of light. (*Méc. Célste*, liv. xvi.)

Another question which may be put with regard to the nature of gravity is, whether its action is in any degree modified by the interposition of the substances through which it penetrates? For example, whether the attractive force of the earth, which must penetrate the whole substance of the moon before its influence reaches the particles on the opposite side of that body, acts with the same intensity on those particles as on those nearest the earth, regard being had to the law of the distance? Now, if the attractive force suffered any diminution in passing through the lunar substance, the parallax would thereby be affected; and, from the amount of the parallax, it is certain that the intensity of terrestrial gravitation on the different molecules of the moon suffers no variation, excepting what arises from the different distances of the molecules. It may therefore be considered, says Laplace, as sufficiently established that the force of gravity is of so subtle a nature that the densest bodies of the universe offer no obstacle to its free passage.

A third conclusion is, that the law of gravity is not modified in any respect by the different natures of the celestial bodies. If the action of the sun on the molecules of the earth differed only by a millionth part from its action on the molecules of the moon, the difference would occasion a variation of the sun's parallax amounting to several seconds. But the supposition of any such variation is impossible. It follows, therefore, that the gravitating force of the sun, in equal times and at equal distances, impresses equal velocities on the earth and moon. It is also demonstrated from the theory of Jupiter

and Saturn, that Jupiter acts on Saturn according to the same law as on his own satellites. Gravity is therefore a force altogether independent of the nature of the substances on which it acts.

GRAVITY, SPECIFIC. The specific gravity of a body is the ratio of its weight to the weight of an equal volume of some other body assumed as a conventional standard. The standard usually adopted for this purpose is pure distilled water at a given temperature. In England, the temperature is generally taken at 62° of Fahrenheit's scale; the French take it at 32°, or that of melting ice; sometimes at the temperature at which its density is the greatest (about 39·4° of Fahrenheit). The latter is by far the more convenient, inasmuch as it can be easily maintained without variations; whereas it is hardly possible to perform experiments at the exact temperature of 62°, in consequence of the continual variations of the temperature of the air. It is only, however, when very great precision is required, that it is necessary to make the experiment with water at any particular temperature; in general, it is sufficient to note the temperature, and apply a correction depending on the known density of water at the different degrees of the thermometric scale.

The most obvious method of ascertaining the *relative weights* or specific gravities of two different bodies is to immerse them successively in a cylindrical or prismatic vessel of a known area, containing a liquid of less density than either. When a solid is immersed in a liquid, the liquid occupies as much more space than it did before as is exactly equal to the bulk or volume of the body; and therefore by immersing equal or known weights of different bodies in a vessel of the form specified, the relation between the heights at which the liquid stands will give the relation between their densities. This was the method proposed by Archimedes for solving the famous problem of the crown of Hero.

The method now employed is susceptible of far greater accuracy. It depends on this principle, that a body when immersed in a fluid loses just as much of its weight as is equal to the weight of an equal volume of the fluid. By weighing a body, therefore, first in air (or rather in vacuo), and then in a liquid, the ratio of its specific gravity to that of the liquid will be found as follows:— Let $s=$ the specific gravity of the body, $v=$ its volume, $w=$ its weight in air, and $W=$ its weight in the liquid; also let $s'=$ the specific gravity of the liquid, and v' and w' be respectively the volume and weight of a given portion of it. Now it is evident, in the first place, that if the volume of a body be supposed constant, its specific gravity will be directly proportional to its weight; and, in the second place, if the weight remains constant, the specific gravity will vary inversely as the volume; that is to say, the smaller the volume the greater is the specific gravity. The specific gravity of a body is therefore directly as its weight, and inversely as its volume. Hence we have

$$s : s' :: \frac{w}{v} : \frac{w'}{v'}.$$

But if we suppose $v=v'$, the weight of the portion of liquid whose volume is v' will be equal, by the principle laid down, to the difference between the weight of the body in air and in the liquid, that is, equal to $w-W$; whence $w'=w-W$, and the proportion becomes

$$s : s' :: w : w - W;$$

from which we deduce $s=s'\dfrac{w}{w-W}$. Now let the liquid be pure water at the standard temperature, then $s'=1$, and we have simply $s=\dfrac{w}{w-W}$; so that in order to obtain the specific gravity of a solid body, its weight in air must be divided by the loss of weight it sustains when weighed in pure water.

The process of finding the specific gravity of any solid body denser than water is rendered very simple by means of the *hydrostatic balance*. When the solid is less dense than water, its weight in that liquid cannot be ascertained directly; but it may be found by attaching the body to another sufficiently dense to cause both to sink. Let $l=$ the weight of the light body in air, and $x=$ its weight in water; $h=$ the weight of the heavy body in air, and $h'=$ its weight in water; $c\ (=l+h)=$ the weight of the compound or united mass in air, and $c'=$ its weight in water. All these quantities are found by experiment, excepting x. Now we have obviously $l-x+h-h'=c-c'$; therefore $l-x=(c-c')-(h-h')$. But if s denote the specific gravity of the light body, we have, by what has already been shown, $s=\dfrac{l}{l-x}$; therefore, $s=\dfrac{l}{(c-c')-(h-h')}$.

In this manner, the specific gravity of a solid in the state of powder may be found by placing it in a vessel whose weight in air and in water has been previously determined.

The specific gravity of a liquid may be found in several ways by means of the hydrostatic balance. Let a solid body of any convenient form, for example a sphere of glass, be taken, and let $w=$ its weight in air, $w'=$ its weight in water, and $w''=$ its weight in the fluid whose specific gravity is to be ascertained; then, taking s to denote the specific gravity of the solid body, s' the specific gravity of water, and s'' the specific gravity of the liquid, we have by the first formula $s=s'\dfrac{w}{w-w'}$, and also $s=s''\dfrac{w}{w-w''}$; therefore $s'\dfrac{w}{w-w'}=s''\dfrac{w}{w-w''}$; and making $s'=1$, we deduce $s''=\dfrac{w-w''}{w-w'}$. It is evident that this process is equivalent to finding the ratio of the density of the solid body first to water, and then to the liquid to be experimented on.

Another method is to take a phial of known weight and weigh it when filled with water; the increase of weight is of course the weight of the water. It is then filled with the liquid, and again weighed, and the weight of the contained liquid thus ascertained. We have then the weights of equal bulks of the water and the liquid, whence the ratio of their specific gravities is known.

For many practical purposes, and especially for determining the specific gravities or *strengths* of spirituous liquors, it is necessary to have recourse to more expeditious methods than that of the hydrostatic balance. In such cases, the instrument called an hydrometer is employed. (*See* HYDROMETER.)

The specific gravities of the gaseous fluids are usually determined in terms of that of atmospheric air. The difference between the weights of a flask when exhausted of air by means of the air-pump and when filled with the gas gives the weight of the gas which it contains. But experiments of this kind require to be made with great care, as they are much affected by small variations of the temperature, pressure, and hygrometric state of the atmosphere. For a detailed account of the method of proceeding, and the manner of applying the requisite corrections, see *Biot's Traité de Physique*, tome i.

The subjoined tables give the specific gravities of the substances which most frequently occur: for a more extended list, we refer to Brisson's Table (*Pesanteur spécifique des Corps*); or to the *Ency. Britannica*, art. "Hydrostatics."

I. Table of the Specific Gravities of Solids and Liquids at the Temperature of 32° of Fahrenheit, the Density of Water being 1.

Acid, Acetic	-	1·062
Arsenic	-	3·391
Arsenious	-	3·728
Benzoic	-	0·667
Boracic, crystallized	-	1·479
fused	-	1·803
Citric	-	1·034
Formic	-	1·116
Fluoric	-	1·060
Molybdic	-	3·460
Muriatic	-	1·200
Nitric	-	1·271
Do. highly concentrated	-	1·583

GRAYLING. *See* SALMO.

GRAZIO'SO. (It.) In Music, an instruction to the performer that the music to which this word is affixed is to be executed elegantly and gracefully.

GREAVE. (Fr. grève.) A piece of armour defending the shin (in the patois of Burgundy, grève still signifies shin). The greave was a piece of steel hollowed to fit the front of the leg, and fastened with straps behind. The Greeks termed them *κνημιδες*, whence the common epithet of *ἐυκνημιδες Ἀχαιοι*, or "well-greaved Greeks," in the *Iliad*. It appears that the greave common among the Greeks was used in some instances by the Roman soldiery, but only on one leg, the other being covered with the buckler. It is said to have been discontinued in the armies of the Greek empire, under the emperor Maurice (about the end of the 6th century), and again brought into use in those armies of the middle ages about 1320. They were also called *jambs*, *bein-bergs*, &c. They were originally of leather, quilted linen, &c. The *clavons* were a species of greaves made of cloth.

GREAVES, or GRAVES. The sediment of melted tallow, composed of the membranous, vascular, nervous, and muscular matters blended with the fat, and which not being fusible, are easily separated from it by straining; they are made up into cakes, and sold by the tallow-chandlers, being chiefly used as a coarse food for large house-dogs.

GREBE. *See* PODICEPS.

GRECIAN ARCHITECTURE. *See* ARCHITECTURE.

GREEK CHURCH, THE, comprises the great bulk of the Christian population of Russia and Greece, Moldavia and Wallachia, besides various congregations scattered throughout the provinces of the Turkish and Austrian empires, who acknowledge the patriarch of Constantinople as their head. This prelate, although possessing a certain spiritual supremacy over this extensive community, has never ventured to assert any claim to the temporal power so long wielded by his rival at Rome. His ambition was curbed in the first instance by the jealousy of the emperors, with whom he was brought into closer contact; and since the Mohammedan conquest the state of weakness and poverty into which the Christian church in Turkey has been thrown has annihilated all views of aggrandizement. In earlier times, however, the Constantinopolitan pontiffs clearly showed that they did not lack the will to raise themselves to an equal station in the East with the growing authority of the popes in the West. The origin of the separation which has now prevailed for many hundred years between two such important sections of Christendom as the Latin and Greek churches, approaching so near as they do in many of their fundamental principles, is to be attributed to the rival pretensions set up by the bishops of the two imperial cities, and dates almost from the foundation of the younger capital.

As early as the year 451 the council of Chalcedon assigned Asia Minor, Pontus, Thrace, and the frontiers of Illyricum for the extent of the spiritual jurisdiction of the church of Byzantium, and conferred upon its bishop the same honours and privileges as had been already conceded to the pope of Rome. The patriarchs of Antioch and Alexandria maintained at this period an independent authority; but were gradually reduced under the predominant influence of the patriarch of the East. The aggressions, however, of the rival pontiffs did not proceed pari passu: the Roman, being further removed from the imperial authority, which was seated at Ravenna, assumed by degrees a direct temporal authority over the neigh-

bouring districts, which led the way to the prodigious indirect supremacy which he usurped after the lapse of several ages. The Constantinopolitan, on the contrary, was always strictly watched, and fettered by the proximity of the Eastern emperors; and the extension or declension of his authority depended in most cases more upon the particular character of the wearer of the crown than of the mitre. The first doctrinal ground of dispute was the assertion of the Latin church, about the beginning of the 9th century, of the double procession of the Holy Ghost from the Father and the Son. The word *filioque*, first surreptitiously inserted into the Constantinopolitan creed many years after its promulgation, became the badge of the Western church; and whatever apparent advantage the shameful forgery above mentioned might give to the opposite party, it is very certain that the other dogma, the procession from the Father alone, had never been declared by a council of the church. And the silence of the symbols upon it was no argument against either the truth of the doctrine, or the fact of its having been held, as much as any doctrine may be said to be so, before it has been brought forward into discussion and settled in men's minds by the great mass of the learned world.

The discussions produced by this controversy were brought to a head by the sudden elevation of Photius, a layman, to the patriarchate, by the command of the emperor. In six successive days he passed through the six preliminary orders: he became successively monk, reader, subdeacon, deacon, priest, bishop, and finally, on the seventh day, was consecrated patriarch; and all this to the violent exclusion of the existing pontiff, Ignatius. The appointment of Photius, who was a man of extraordinary talents, alarmed the Romish see. The cause of Ignatius was supported in the West; and the intruder excommunicated by Nicholas I. The thunder of Rome was retorted by a charge made on the part of Photius against the Latin church of five distinct heresies; which it may be as well to enumerate, in order to show the frivolity of the greater part of the grounds of dispute at this period. 1. It was objected that the Romanists fasted on the Sabbath, or seventh day of the week; 2. That they permitted the use of milk and cheese in the first week of Lent; 3. That they forbade their priests to marry; 4. That they authorized bishops to baptize with the chrism, and forbade the priests; 5. That they had interpolated the creed of Constantinople with the word *filioque*, and held the doctrine therein implied.

These proceedings widened the breach which had already in fact taken place by the formal transference which the emperor had effected of several provinces east of the Adriatic, from the jurisdiction of Rome to that of Constantinople. The Roman party continued, however, still powerful in the East, and the intrigues of the papal see were frequently successful; until in 1054 the mutual excommunications pronounced upon each other by Leo IX. and Cerularius caused the final separation, which has continued to the present day.

The opinions of the Greek church bear considerable affinity to those of the Latin. The fundamental distinction is the rejection of the spiritual supremacy of St. Peter, and the denial of any visible representative of Christ upon earth. In the view which it takes of the procession of the Holy Ghost it is at variance not only with the Roman Catholic church, but with Protestants also. It recognizes, however, the seven sacraments; authorizes the offering of prayer to the saints and Virgin; and encourages the use of pictures, though forbidding that of images. It holds in reverence also the relics and tombs of holy men; enjoins strict fasting and the giving of alms, looking upon them as works of intrinsic merit; and numbers among its adherents numerous orders of monks and nuns. It allows, however, the marriage of its secular priests, and rejects auricular confession. It holds that modified form of the Roman doctrine of the eucharist which is denominated consubstantiation; and apparently entertains some confused notions of a purgatory, in consideration of which it offers prayers for the dead. It administers baptism by immersion.

The services of this church mostly consist of ceremonial observances; preaching and the reading of the scriptures form but a small part of them: the former, indeed, was at one period altogether forbidden in Russia. The mass of the people are in a state of the grossest ignorance upon religious subjects; and the worship of the lower orders, under the influence of a poor and unlettered ministry, is hardly distinguishable from the grossest heathenism.

GREEN CLOTH, BOARD OF. A court of justice belonging to the king's household, daily sitting in the king's palace, under the lord high steward. It is attended by various officers of the household, and by the steward of the Marshalsea, who is always a barrister. They meet for the purpose of taking daily accounts of expenses, making provision and payments for the household, and paying the wages of the king's servants under the lord high steward. It has jurisdiction in all offences committed in the king's palaces, and within the verge of his court.

GREEN-HOUSE. In Gardening, a house with a roof and one or more sides of glass, for the purpose of containing plants in pots which are too tender to endure the open air the greater part of the year. The green-house, being a structure of luxury, ought to be for the most part situated near the house, in order to be enjoyed by the family in inclement weather; and, if possible, it should be connected with the flower-garden, as being of the same character with reference to use. Its length and breadth may be varied at pleasure, but its height should never be less than that of the loftiest apartments of the house to which it belongs. The best aspect is to the south or south-east; but any aspect may be chosen, provided the roof is entirely of glass, and abundant heat is supplied by art. In green-houses facing the north, however, the more tender plants will not thrive so well in winter: more artificial heat will be required at that season; and the plants should be chiefly evergreens, and other plants that come into flower in the summer season, and grow or flower but little during winter. In most green-houses the plants are kept in pots or boxes, and set on stages or shelves, in order that they may be near the roof, so as to receive the direct influence of the rays of light immediately on their passing through the glass. An orangery differs from a green-house in having an opaque roof, and in being chiefly devoted to plants which produce their shoots and flowers in the summer season and in the open air; and they are set in the orangery merely to preserve them through the winter. Such a structure might with more propriety be termed a conservatory; but custom in the present day has applied this term to structures having glass-roofs in which the plants are not kept in pots, but planted in the free soil, and in which a part of them are encouraged to grow and flower in the winter months. *See* ORANGERY and CONSERVATORY.

GREEN ROOM, in the Theatre, the name given to the actors' retiring room; so called, in all probability, from its being originally painted or otherwise ornamented with green.

GRE'ENSAND. Beds belonging to the chalk formation: they often contain *chlorite* or *green earth* scattered through the sandstone and limestone of which they consist. *See* GEOLOGY.

GREEN, SCHEELE'S. An arsenite of copper. *Mineral green* is a subcarbonate of copper, and *Brunswick green* an oxychloride of copper.

GREEN SICKNESS. *See* CHLOROSIS.

GREENSTONE. A variety of traprock composed of felspar and hornblende. *See* GEOLOGY.

GREEN VITRIOL. The metallic salts of sulphuric acid were formerly designated *vitriols:* sulphate of iron was termed *green vitriol*. It is a compound of 1 atom of oxide of iron and 1 atom of sulphuric acid: the crystals contain 7 atoms of water; hence the crystallized salt consists of 36 protoxide of iron, 40 sulphuric acid, and 63 water, and its equivalent is =139. Sulphate of copper is called *blue vitriol*, and sulphate of zinc *white vitriol*.

GREGO'RIAN CALENDAR. The reformed calendar of the church of Rome, introduced by Pope Gregory XIII. in 1582, in which the error of the civil year of the Julian calendar was corrected by the omission of three intercalary days in four centuries, and the moon's age, with the time of Easter, with the other moveable feasts depending on it, indicated by the table of epacts. *See* CALENDAR.

GREGO'RIAN EPOCH. The epoch or time at which the computation by the Gregorian calendar commenced. This was in March, 1582.

GREGO'RIAN TELESCOPE. The first and most common form of the reflecting telescope, invented by James Gregory, professor of mathematics in the university of St. Andrew's, and afterwards of Edinburgh, and described by him in his *Optica Promota*, published in 1663. *See* TELESCOPE.

GREGO'RIAN YEAR. The civil year of the Gregorian calendar. In the Gregorian calendar the common year consists of 365 days, and every fourth year is a leap year, or contains 366 days, excepting the last years of every century of which the number is not divisible by 4. Thus, the years 1700, 1800, 1900, are not leap years; but 1600 and 2000 are leap years, the numbers 16 and 20 being divisible by 4. The period is consequently 400 years, in the course of which there occur 97 intercalations; so that 400 years contain $365 \times 400 + 97 = 146097$ days, and therefore one Gregorian year consists of 365·2425 mean solar days, or 365 d. 5 h. 49 m. 12 sec. But the true solar year consists of 365 d. 5 h. 48 m. 49·62 sec. The Gregorian year, therefore, errs in excess by 22·38 seconds; but the error is not worth taking into account, as it only amounts to one whole day in 3866 years.

GRENA'DE. A hollow ball of iron about two inches and a half in diameter, charged with gunpowder and furnished with a proper fuse; it is often called a hand grenade, being thrown from the parapets of besieged places upon the invaders beneath.

GRENADI'ERS, was the name given at first to the soldiers who threw the grenade; but it was afterwards

conferred on certain troops of the line, distinguished from the latter chiefly by some peculiarities of dress, accoutrements, &c. This appellation originated with the French in 1667, but was speedily adopted into all the armies of Europe; and wherever the name has been introduced, the finest-looking and tallest men of the regiment have always been selected to form what is called the grenadier companies.

GRE'S. (Fr.) Sandstone or grit.

GRESSO'RIAL, in Ornithology, is applied to the feet of birds which have three toes forward, two of which are connected, and one behind.

GRETNA GREEN MARRIAGES. A species of marriage, so called from its being usually celebrated at that place. The following statement, which we have borrowed from the *Geographical Dictionary*, conveys so full and accurate particulars of these far-famed marriages, that we have taken the liberty of transferring it to our columns.

"The marriage ceremony merely amounts to an admission before witnesses that certain persons are man and wife; such acknowledgment being sufficient, *provided it be followed or preceded by cohabitation*, according to the law of Scotland, to constitute a valid marriage. A certificate to this effect being signed by the officiating priest (who has never been above the rank of a tradesman), and by two witnesses, the union, under the above condition, becomes indissoluble. The marriage service of the church of England is sometimes read, in order to please the parties. The marriages of this sort celebrated at Gretna Green are estimated at between 300 and 400 a year; but as similar marriages are celebrated at Springfield, Annan, Coldstream, and other places along the border, their total number is said to amount to 500 a year! The parties are generally from England, and of the lowest ranks; though there are not a few instances of persons of the higher ranks, and even of lord chancellors, having had recourse to the services of the *soi-disant* parsons of Gretna Green. A trip to Gretna, or the presence of a self-dubbed parson, is not, however, at all necessary. Parties crossing the Scottish border, and declaring before witnesses that they are man and wife, are, under the previously mentioned conditions, married according to the law of Scotland. This law has been much objected to, but we are inclined to think with no good reason. It would, indeed, be no difficult matter to show that it is, on the whole, productive of numerous advantages. No where, perhaps, are there so few rash or improvident marriages as in Scotland; and the retrospective effect of the existing law, or its influence in legitimising the children born before marriage, is perhaps its most valuable feature. But it is necessary to observe, that though legitimated in Scotland, children born previously to a Scotch marriage are not legitimated in England, and do not succeed, except by special bequest, to heritable property in that part of the U. Kingdom. In all respects, however, Scotch marriages convey the same rights and privileges in England as English marriages. The practice began at Gretna Green about 90 years ago by a person named Paisley, a tobacconist, who died so lately as 1814. It is now carried on by various individuals: indeed each inn has its rival priest, in addition to others who carry on the business on their own account; and so far has competition reduced the fees, that though large sums (40*l.* or 50*l.*) have been received, the solatium, in some instances, is now so low as half-a-crown. One of these functionaries, who breaks stones daily on the verge of England, has the best chance of succeeding; for he accosts every party as they pass, and tries to strike the best bargain."

GREYWACKE. *See* GRAUWACKE, GEOLOGY.

GRI'FFIN. (Gr γρυψ.) A fabulous animal of antiquity represented with the body and feet of a lion, the head of an eagle or vulture, and as being furnished with wings and claws. The griffin is one of those imaginary creations to which the ancients were so confessedly partial, but it belongs more to the romantic than the classical mythology. It plays a prominent part in the fairy tales and romances of the middle ages; and, like the dragon which was fabled to guard the golden apples of the Hesperides, its chief duties consisted in watching over hidden treasures, and in guarding captive princesses, or the castles in which they were confined. The griffin is at once the symbol of strength and swiftness, courage, prudence, and vigilance—qualities which its form is well calculated to represent; and hence it has been adopted into the language of heraldry, where it constitutes a prominent feature in the armorial bearings of many princely and noble families.

GRIMA'CE. (Fr.) In Painting and Sculpture, an unnatural distortion of the countenance, from habit, affectation, or insolence.

GRIPE. The fore part of a ship. — *To gripe*, the tendency af a ship to bring her head up to the wind when carrying sail on the wind.

GRIT. Hard sandstone, employed for millstones and grindstones, pavement, &c.

GROAT. An old English silver coin equal to 4*d.* of our present money. It was introduced by Edward III. about the year 1351, and has lately been again adopted and issued from the mint: the first coinage of these modern silver groats or four-penny pieces took place in 1835.

GROATS, in Agriculture, are the small grains formed from oats by being cut in the mill, after having the husks or shells taken off from the grain.

GROIN. (Sax. ʒnopꞇn, *to grow.*) In Architecture, the line formed at the intersection of two arches which cross each other at any angle.

GRONI'NGENISTS. In Eccl. History, a subdivision of the sect of Anabaptists. (See *Mosheim*, Transl., vol. v. p. 492.)

GROOM. A name now usually applied to servants who are employed about horses. From the Flemish grom, *a boy*. The *groom-porter* was an officer of the royal household in the lord steward's department, whose place is said to have succeeded that of the master of the revels. Groom is still the denomination of several officers of the royal household, chiefly in the lord chamberlain's department; such as grooms in waiting, groom of the stole or robes, &c. &c.

GROOVE. (Sax. ʒpaꝼan, *to dig.*) In Architecture, a sunken rectangular channel. It is usually employed to connect two pieces of wood together, the piece not grooved having on its edge a projection or *tongue*, whose section corresponds to and fits the groove.

GROSS. In Commerce, the number of 12 dozen.

GROSSULA'CEÆ. (Grossularia, one of the genera.) A natural order of shrubby Exogens, natives of most parts of the world, excepting Africa and the tropics; formerly confounded with *Cactaceæ*. Placed by Von Martius between *Saxifragaceæ* and *Onagraceæ;* but nevertheless, on account of their albuminous seeds, appearing to have affinities of another nature, especially with *Berberaceæ* and the vine. The gooseberry and currant are fruits of this order, to which many beautiful hardy shrubs common in our gardens also belong.

GROSSULA'RIA. (Lat. grossula, *a gooseberry.*) A green garnet found in Siberia.

GROTE'SQUE. (Fr.) In the Fine Arts, a term applied to capricious ornaments, which as a whole have no type in nature; consisting of figures, animals, leaves, flowers, fruits, and the like, all connected together.

GROTESQUE. In Architecture, artificial grotto-work decorated with rockwork, shells, &c.

GROTTO. (It.) The name given to subterraneous natural excavations formed in the heart of mountains or other places. Many of these cavities are famed for the mephitic exhalations that issue from them, and to this class belongs more especially the Grotto del Cane, near Naples; but there others not less celebrated for their beauty and grandeur, of which the grottoes of Antiparos and Fingal are well-known examples. In picturesque gardening, the term is applied to an artificial or ornamental cave or low building intended to represent a natural grotto. The best specimen of this kind is the grotto attached to the Colosseum, which may be considered a model for all similar designs.

GROUND. (Sax. ʒpunꝺ.) In the Fine Arts, a word of various application. In Painting, it is the first layer of colour on which the figures or other objects are painted; in Sculpture, it is the surface from which, in *relievi*, the figures rise; and in Architecture, it is used to denote the face of the scenery or country round a building.

GROUND BAIT. Balls made of greaves, bran, boiled grain, gentles, &c., mixed up with clay and thrown into the water, by which the fish are brought together upon those spots which the angler selects for his sport.

GROUND PLATE, or SILL. In Architecture, the lower part of a timber building, which receives the principal and other posts.

GROUNDS. In Architecture, pieces of wood flush with the plastering, for which they serve as a guide, &c., to which mouldings and other finishings are attached.

GROUP. (Fr. groupe.) In Painting, an assemblage of objects, whose lighted parts form a mass of light, and their shaded parts a mass of shadow: the word is also used to denote any adjoining assemblage of figures, animals, fruits, flowers, &c. In speaking also of objects of different sorts, it is usual to say that one object *groups* with another. Lights in groups should, as well as shadows, be connected together, or the necessary repose will be wanting. In Sculpture, the word *group* is applied to a design in which there are two or more figures. In Music, *group* signifies a number of notes linked together at the stems.

GROUSE. *See* TETRAO.

GROUT. (Sax. ʒpuꞇ.) In Architecture, mortar reduced to a state of fluidity by the addition of water: a mixture of plaster and fine stuff, putty, or coarse stuff, used in finishing the best ceilings; also for mouldings, and sometimes for setting walls.

GRU'IDÆ. The name of the family of wading birds represented by the stork (*Grus*).

GRUS. (Lat. the *Crane.*) One of the modern constellations in the southern hemisphere. *See* CONSTELLATION.

GRY'LLIDÆ. (Lat. gryllus, *a locust.*) The name of the family of locusts, having the genus *Gryllus* for the type.

GRYPA'NIUM. (Gr. γρυπος, *incurved.*) In Ornithology, the *rostrum grypanium* is that form of beak in which the culmen is more or less carinated, and is so continued to the apex of the incurved maxilla.

GRYPHÆ'A. (Gr. γρυπος.) A genus of Ostracean Bivalves, remarkable for the curvature of the apex or beak of the shell; it is chiefly represented by fossil species, one of which, *Gryphœa virgula*, characterizes the Kimmeridge clay, near Oxford, and the upper oolite of parts of France.

GRYPHO'SIS. (Gr. γρυποειν, *to incurvate.*) A growing inwards of the nails.

GUA'IACUM, is a peculiar resinous substance obtained from the *Guaiacum officinale*, a tree of the West Indies. It has some chemical peculiarities which distinguish it from the common resins, especially its property of becoming blue and green by the action of certain oxidizing substances. Decoction of the wood of the tree, and the tincture of the resin, have been employed in the cure of rheumatism, and as an alterative; but it is an unimportant medicine.

GUA'NO. A substance found upon certain small islands, especially in the South Sea, which are the resort of large flocks of birds, and chiefly composed of their excrement: it is said to form beds fifty to sixty feet in thickness. It is an excellent manure.

GUARANTE'E, in Law, is an undertaking to answer for the failure of another. By the Statute of Frauds, a person is not liable on a special promise in the nature of a guarantee unless a written agreement, or memorandum of such promise, shall be signed by the party making the promise, or some person lawfully authorized by him.

GUA'RDIAN, in Law, he who has the custody of such persons as are incapable of directing themselves, and especially of infants. Guardians at common law were—1. In chivalry (under the feudal principle of wardship, abolished with the other incidents of military tenure by 12 Ch. 2.). 2. By nature; the father in all cases; the mother to daughters, where no guardian is assigned by the father's deed or will. 3. For nurture; appointed by the ordinary in default of father or mother. 4. In socage, being the nearest of kin to an infant entitled to real estate who cannot inherit that estate.

GUA'RDIAN OF SPIRITUALTIES. In Ecclesiastical Law, the person to whom the spiritual administration of a diocese is entrusted during the vacancy of the see.—Of *Temporalties*, one appointed by the king during such vacancy to take care of the goods and profits, and deliver an account to the Exchequer.

GUARD, NATIONAL, OF FRANCE. This famous institution was first devised by the Municipal Committee of Safety of 1789, which sate at the Hôtel de Ville, in Paris, before the taking of the Bastille. The corps which was then raised at first carried green colours, afterwards replaced by the tricolor. It was more fully organized by a decree of September, 1791, to be raised by voluntary enlistment, both in Paris and the departments, in the proportion of one man out of every twenty citizens. The staff of the national guard was dissolved by the Convention after the 13 Vendémiaire (1795), and it was placed under control of the military authorities. Napoleon made of the national guard a species of military nursery, and large portions of it volunteered in 1813 to act beyond the frontiers. Under the Restoration the national guards were deprived of the privilege of choosing their own officers; and in 1827, in consequence of their public demands for the dismission of the ministry (Villele's), they were dissolved. By their constitution, as remodelled in 1830, they elect their own officers up to the rank of sublieutenant inclusive: the rest are appointed by the king.

GUARD, THE IMPERIAL, in the armies of the Emperor Napoleon, was formed from a small corps of lifeguards (as they might be termed) which had served to defend the Convention, the Corps Legislatif of 1795, the Directory, and afterwards the Consulate. In 1805, when Napoleon became emperor, the consular guard had already been increased to 3300 infantry and 2100 cavalry, besides artillery and marines. Its augmentation and equipment became afterwards one of Napoleon's favourite pursuits; and as soldiers could not be enrolled except after serving four campaigns in the line with distinction or from the preparatory corps called the young guards, it was an institution of the highest military policy. In the end of 1812, the Imperial Guard, old and young, consisted of 56,000 men; and its farther increase was only prevented by the calamities of the following years. At the Restoration, the soldiers of the young guard returned to the line; those of the old guard were formed into royal regiments.

GUARD, YEOMEN OF THE, were first raised by Henry VII. in 1485, and appear to have been the first standing military corps ever set on foot in this country. They were at first fifty men, half armed with bows and arrows, and half with arquebusses; afterwards some carried halberds. The arquebusses were exchanged for partizans (which they now carry) in the reign of William III.

GUARDS. Troops attached to the person of the sovereign. In modern times, the designation is applied in most countries to a body of men distinguished from the line by difference of pay, dress, &c., and possessing a certain military rank. Body-guards have been an inseparable accompaniment of monarchy from the earliest ages: the Assyrian and Persian monarchs employed them. The corps of Argyraspides, or silver-shields, were selected by Alexander out of the bravest men of his army. The Roman emperors had their Prætorian guard. Napoleon first created a small troop of body-guards, with the title of Guides, while yet only general, in his first Italian campaign. From this arose by degrees the great institution of the Imperial Guard, itself an army, with its two great divisions of old and young, and 120 pieces of cannon; the whole of which corps was broken up at the Restoration. On the revolution of 1830, the royal guards of France were disbanded, and none have been since embodied in that country. In England, the guards (otherwise called household troops) consist of the life-guards, the royal regiment of horse-guards, and three regiments of foot-guards. Many of the European sovereigns, before the French Revolution, had small corps of foreign troops which served in this capacity. Thus the French kings had, in early times, a body of Scotch guards, termed archers; at a later period, a body of Swiss guards, called the Cent-Swisses; and after the Restoration of 1815 several battalions of Swiss guards were organized for the same service. This system has almost disappeared, since the troubles of the Revolution have introduced a spirit at once more military and more national into the councils and populations of Europe. The Pope still retains his Swiss guards.

GUA'VA. The fruit of the *Psidium pomiferum*, from which a jelly is made in the West Indies.

GU'DGEON. The common name of a small species of the Cyprinoid family of soft-finned fishes; having, like the barbel, cirri or feelers at the mouth, and both the dorsal and anal fins short, but without a strong bony ray at the commencement of either. The species consequently forms the type of a distinct subgenus called *Gobio*.

GU'DGEONS. In Machinery, the pins inserted in the extremities of a shaft, or the axle of a wheel, on which it turns, and which support the whole weight. In order to diminish friction, gudgeons are made as small as possible in diameter; leaving, however, sufficient strength to support the weight. They are frequently formed of cast iron, on account of its cheapness; but wrought iron of the same dimensions is considerably stronger, and will support a greater load.

GUE'BERS, or GUEBRES (*i. e.* Giaours, *infidels*). The sectaries of the ancient Persian religion, of which the chief peculiarity consisted in the worship of fire, are so termed by the Mohammedans. They still exist in some of the southern and eastern districts of Persia; but a colony of them has been long established at Bombay, and other parts of the western coast of India, and has attained to wealth and distinction. These are termed in India *Parsees*, from the nation from which they originally sprang. The Guebres explain the worship of fire by professing to regard it as a symbol only of the Divinity. Their sacred books are termed the Zend-Avesta. *See* PARSEES.

GUELF, ORDER OF, or ROYAL GUELPHIC ORDER. An Hanoverian order of knighthood, founded in 1815 by George IV., then Prince Regent. It consists of grand crosses, commanders, and knights, both civil and military.

GUELFS. In Italian History, during the middle ages, a political party, the feuds between which and the opposite party of the Ghibellines long distracted that country. The former name is derived from that of the great German house of the Welfs or Guelfs. These, in the 12th century, were dukes of Bavaria; and carried on war in Germany with the house of Hohenstauffen, from one of whose castles (Weiblingen) the name Ghibelline is supposed to have been derived. The latter house having become the ruling power in Germany under Frederic I., that prince invaded Italy in order to reassert the rights of the empire; and thus these party names, first used in a German feud, were transplanted into that country. The chief adversaries of the house of Hohenstauffen in Italy were the Popes, who thus became the heads of the Guelf party; and the struggle between the two became, in the 13th century, when Frederic II. was involved in contests with several successive pontiffs, a contest between the temporal and spiritual power. In that instance the latter prevailed; but the Ghibellines remained, notwithstanding, powerful, especially in the north of Italy; and, in the beginning of the following century,

the invasion of the emperor Henry of Luxemburg added considerably to their power. In the early part of that century the leading Ghibelline powers generally were, Milan under the house of Visconti, Verona under that of La Scala, and the Aragonese kings of Sicily; the chief Guelf states the republic of Florence, the Angevin kings of Naples, &c. Other states were alternately under the control of the two parties as they in turn predominated. At this time the poet Dante, who had embraced Ghibelline principles, not merely on party grounds, but from exalted political speculation, threw the lustre of his genius over the civil feuds of his age. In the course of the 14th century, especially after the removal of the papal seat to Avignon, the original principles of the two parties were entirely lost; while the names continued, and factions bearing those appellations constantly agitated the interior of Italian cities and monarchies down to the middle of the 15th century, or even to a still later period. The most complete works which can now be consulted on the subject are those of Raumer (*Geschichte der Hohenstauffen*), and Sismondi (*Républiques Italiennes*).

GUERRI'LLA. (Span. *little war.*) The plan of harassing the French armies by the constant attacks of independent bands, acting in a mountainous country, was adopted in the north of Spain during the Peninsular war. It was first reduced into a kind of system in 1810. (See *Napier's Peninsular War*, book ix. chap. 1.) The bands which conducted this desultory warfare were called Partidas: the name of Guerrilla is, by a misapplication of the term, frequently applied to them.

GUIDE. (Fr.) In Music, the leading part in a canon or fugue.

GUILD, or GILD. (Sax. gildan, *to pay*: said to be derived from payments made by a member of a guild on admission.) A fraternity or association, generally of merchants. The Collegia Opificum of the later Roman empire appear to have been societies of this description, in which a body of artizans or traders exercising the same craft were united together for purposes of mutual assistance, and possessed what we should term corporate rights. The Anglo-Saxon guilds were voluntary associations for various purposes, religious and social as well as commercial; and the oldest English guild of which the history is at all ascertained is said to have been the Cnighten guild of London, which has been thought by its name to have been a military company; but this is doubtful, and its history is altogether extremely obscure. But the more important guilds of later times have been all mercantile. The guild-merchant, in many boroughs of England, seems to have been a trading society, into which all persons wishing to exercise trade within the borough were obliged to be admitted; and hence, in process of time, the freedom of the borough, which originally depended upon mere inhabitancy, became connected with admission to the guild, and the guild and corporate body of the borough became co-extensive. A more remarkable change took place in the constitution of London, where the several trading companies by degrees so completely engrossed the government that admission into one or the other of them (the liveried companies) became a necessary qualification for the exercise of municipal rights; while some relics still remain (such as the division of the city into wards) of the more ancient state of things. The name guild is still preserved in the ancient boroughs of Scotland, and the dean of guild is the second municipal magistrate of a Scottish borough. The zünfte of German cities, and the trading companies of those of France and Italy, have acted an equally important part in the history of those countries.

GUILLEMOT. *See* Uria.

GUILLOCHE. (Fr.) In Architecture, an ornament composed of curved fillets, which by repetition form a continued series.

GUILLOTI'NE. (Fr.) The name given to the instrument of capital punishment used in France; so called from Joseph Ignace Guillotin, by whom it was introduced into that country. This person was born at Saintes, and, established as a physician at Paris, obtained a certain celebrity in the early period of the Revolution by the strong part which he took in favour of the rights of the Tiers-Etat. He was elected in consequence a deputy to the National Assembly. When that body was occupied in its long discussions relative to the reform of the penal code (in 1790) Guillotin proposed the adoption of decapitation, — up to that time used only for nobles, — as the only method of capital punishment. From sentiments of humanity he recommended the employment of a machine which had been long known in Italy under the name of "mannaja," and in other countries also; for something much resembling it had been used in Scotland (*see* Maiden), and in England within the jurisdiction of the borough of Halifax. The Assembly applauded the idea, and the machine was adopted, to which the Parisians have given the name of "Guillotine," and of which Guillotin is most erroneously supposed to have been the inventor. It consists of two upright pieces of wood fixed in a horizontal frame; a sharp blade of steel moves up and down by means of a pulley in grooves in the two uprights; the edge is oblique instead of horizontal in shape, which gives it the mechanical power of the wedge. The criminal is laid on his face, his neck immediately under the blade, which severs it at a blow from his body. It is equally a vulgar error that Guillotin perished by the instrument which bears his name. He was imprisoned during the Reign of Terror, but released at the revolution of July 1794; and died in 1814, after founding the association termed the Academy of Medicine.

GUI'NEA. An English denomination of money; formerly a coin, but now disused. Its value is 21*s*. The coin weighed 129½ grains, and contained 118·7 grains of pure gold. Guineas were first coined in the reign of Charles II. (1662) of gold brought from Guinea; whence the name.

GUI'NEA PEPPER. A species of *capsicum*.

GUI'NEA WORM. The *Filaria medinensis*. A worm which affects the skin, especially of the legs, in warm climates. Whilst it remains under the skin this worm produces little uneasiness, till a part suppurates, and it puts out its head; much pain being experienced on attempting to draw it out, especially if it be broken.

GUITA'R. (It. chitarra.) A musical stringed instrument, whose invention is attributed to the Spaniards. The strings are stretched over a body much larger than the violin, but of somewhat similar shape; except that the sharp corners are rounded off, and the strings, which are more in number than the violin, and are not carried over a bridge, are struck or pulled with the fingers.

GU'LA, in Zoology, is the region of the throat nearest the lower jaw.

Gu'la. In Architecture. *See* Gola.

GULES. (Fr. gueule, *a throat.*) In Heraldry, red; one of the colours, or tinctures, employed in blazonry. It is equivalent to ruby among precious stones, Mars among planets. In engraving it is represented by a vertical line.

GULL. *See* Larus.

GULPH. In Geography, an arm of the sea extending more or less into the land, and distinguished from a *bay* only in being of greater size and extent than the latter. It is derived from the Gr. κολπος, signifying *bosom*, and has been adopted with a slight variation into all the languages of modern Europe.

GUM. A vegetable product, distinguished by solubility in water, and insolubility in alcohol; it is tasteless and inodorous. Gum-arabic, which is the produce of the *Acacia vera*, may be taken as a sample of the purest form of gum. It is imported from Barbary and Morocco. Its specific gravity is 1·45. Its solution is viscid, and is termed *mucilage*. Gum is used as a demulcent in medicine, and for giving gloss and stiffness to linens, silks, &c. It consists of carbon 41·4, oxygen 52·09, hydrogen 5·51; or, in other terms, of 41·4 charcoal and 58·6 water.

GUM-RESIN. An exudation from many trees, composed of a mixture of gum and resin, or of a substance intermediate between the two.

GUN. Under this general term most of the species of firearms are included, the pistol and mortar being almost the only exceptions. Great guns, or cannon (*see* Cannon), began to be used as military engines about the middle of the 14th century; but small guns, or muskets, appear to have been introduced nearly two centuries later, namely, 1521. They were first used by the Spanish infantry at the siege of Rhege Muskets were at first of a very clumsy construction, being so heavy that they could not be levelled and fired from the shoulder; accordingly the soldier was provided with a rest, which it was necessary to carry along with him and plant in the ground in order to support the weapon before it could be used. The gun was generally fired with a match; sometimes by means of sparks generated by the revolution of a notched wheel of steel, placed directly above the pan containing the priming. Muskets with rests were employed so late as the civil wars in the time of Charles I.; afterwards a lighter matchlock musket came into use; and about the beginning of the last century the troops throughout Europe were armed with firelocks.

The barrel forms the essential part of the gun; and the first requisite to a good barrel is toughness in the material of which it is made, for safety in using it depends mainly on this quality. The best iron for the formation of musket barrels is that which has been much worn, and toughened by the loss of its fiery particles; and, accordingly, old horse stub-nails are much in request for this purpose, and sold at a high price to the barrel-forgers. Formerly the best gun barrels were made in Spain; and their superiority was attributed to the excellency of the iron made use of, which consisted almost exclusively of stub nails, and the old shoes of the horses and mules: but the barrels now made in this country are not inferior to those of any country in the world. The method of making the barrel is this: — the iron is first formed into a thin flexible bar, something like a cooper's

hoop, and when heated is plied or twisted round a mandril, much in the same manner as a ribbon of leather is turned round the handle of a whip. For the best barrels the breadth of the bar does not exceed half an inch; and it is turned round the mandril in such a manner that the edges are brought close together, but do not overlap. In this position it is welded by horizontal strokes with the hammer. But in common guns a broader bar is employed; and its edges, which are placed so as to overlap considerably, are welded down on each other. The Damascus barrels, prized for their beauty, though inferior in strength, are composed of iron and steel in certain proportions laid crossways, and hammered together the whole length of the barrel. After the barrel has been forged, the inside is rendered smooth and perfectly cylindrical by boring it with a bit, or rather bits of different sizes used in succession. In rifles a certain number of parallel grooves, either straight or slightly twisted, are cut in the inside of the barrel, of equal depth and fineness, and through its whole length. The exterior is smoothed by turning it on a lathe.

By act of parliament every gun barrel offered for sale must be tried by a certain quantity of powder and weight of shot according to its size; but the best gun-makers do not trust to this legal test, and subject them to a severer trial by water-proof. For fowling pieces and other guns of the best description the flint lock is now laid aside, and the percussion or detonating lock almost universally substituted. This ingenious invention belongs to a Scottish clergyman, the Reverend Mr. Forsyth, minister of Belhelvie in Aberdeenshire; but it has since received some great improvements, especially in the application of the copper cap,— to which indeed may be attributed all its superiority. The following are the dimensions of the new pattern musket carried by the British troops: —

Length of the barrel, in inches - - -	42
Diameter of the bore - - - - -	·75
Diameter of the ball for service - -	·676
Weight of the ball for service, in ounces avoirdupois - - - - - - -	1·06
Weight of the firelock with bayonet, in pounds avoirdupois - - - - -	12·25
Length of barrel and bayonet, in inches -	59

The carbine carried by regiments of light cavalry is 16 inches in length, and weighs 6 pounds. (*Encyc. Brit.*, art. "Gun-making.")

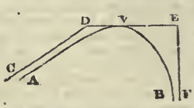
Great guns, or cannon, used formerly to be very long in the bore, and constructed with a view to support large charges of powder; but the experiments of Robins and Hutton proved that neither great length of the bore nor large charges are ever necessary. In consequence of these experiments, a great improvement took place in the artillery services of Europe about the beginning of the French revolutionary wars. The best length has been found to be about 17 calibres. No field-piece has now a bore of more than 18 calibres in length. In the English service the regulation length is 14 calibres; in America, during the late war, it was reduced to 12; but has since been increased, on what principle it does not appear, to 18. The length of the gun must, however, be regulated in many cases by the service for which it is destined. In battering guns a certain length in front of the trunnions is absolutely necessary; for, generally speaking, they are fired from embrasures of earth, which would be injured by the firing if the mouth of the gun did not reach beyond it. Navy guns should also project to a certain distance beyond the side of the vessel, and the same reasons apply to garrison as to battering guns.

With regard to the shape of guns, it is easy to see that it ought to be such as to give them the greatest strength at the part which suffers the greatest strain in firing. This is probably at the part where the ball is lodged. Count Rumford therefore proposed to make the thickness of the metal greatest at this point, and planned a gun swelling in a curve from the breech to the lodgement of the ball, and again contracting in a curve from that point to the projection of the muzzle. In some guns, as the American navy 32-pounder, the form is cylindrical from the base ring to the trunnions, and thence conical to the swell of the muzzle. In respect of British guns, the proportion of the weight of metal of an iron gun is to that of the shot, in heavy guns, as about 224 to 1 or 2 cwt. to 1 lb.; in medium guns as 168 to 1, and in light guns 112 to 1. The length of a 32-pounder, used in the lower deck of line-of-battle ships, is 9 ft. 6 in., and its weight 55 cwt., being about 192 times that of the ball. The medium 12-pounder brass gun is 6 ft. 6 in. in length, weighs 18 cwt., and has a calibre of 4·6 in. in diameter. The length of brass 18, 12, 9, 6, and 3 pounders is 17 calibres. (See *Ency. Brit.*, "Gunnery.") The greater quantity of metal at the breech of a gun than at the muzzle not only gives greater strength to the gun at the part where the danger of bursting is the greatest, but also tends to diminish the force of recoil.

GU'NNER. The first of the three warrant officers of a king's ship. He has the charge of the ordnance, ammunition, and other duties.

GU'NNERY. A branch of the military art, which has for its object the management of guns and mortars, and of charging and directing them so as to hit a proposed mark at any distance within the range of the shot. To accomplish this purpose, it is necessary to know the nature of the path which a projectile describes in the air with a given initial velocity, the quantity of gunpowder necessary to produce that velocity, and the elevation that must be given to the gun in order to counteract the effect of gravity and the resistance of the air on the ball in its flight. Various other considerations require also to be attended to; as the proportion between the length of the gun and the diameter of its bore, the proper *windage* or excess of the diameter of the bore above that of the ball, and the size or weight of the ball proper to produce a certain effect, — to batter down a wall, for example, or to penetrate a ship's side. The method of mounting and working guns, so as to render them most serviceable in military operations, belongs to the head ARTILLERY.

If we abstract from the effect of the resistance of the air, the path described by a projectile is easily determined. The only force which acts on the ball to deflect it from the straight line in which it is projected is gravity, and it consequently describes an arc of a parabola. (PROJECTILE.) But any deductions from the parabolic theory of projectiles are of little or no use in the actual practice of gunnery; for in consequence of the great resistance which the air opposes to a body moving through it with the velocity of a cannon ball, the circumstances of the motion are completely changed. In the parabolic theory, the motion of the ball in the horizontal direction is assumed to be constant and uniform. But the resistance of the air brings another force into action, the intensity of which depends on the velocity of the ball, and which is exerted in a direction exactly opposite to that of the ball's motion; hence the velocity of the ball is continually diminished through its whole course, and in consequence the ascending and descending branches of the trajectory, AV and VB, are unequal and dissimilar. Instead of being branches of the same parabola, they become different arcs of the hyperbolic kind, having asymptotes, CD and EF, dissimilarly situated; the former being inclined to the horizontal line DE, and the latter perpendicular to it.



The motion of the ball in its ascent, being opposed by the resistance of the air as well as by gravity, will neither ascend so high nor range to so great a distance as in the parabolic theory; and in descending through the branch VB its motion downwards is constantly accelerated by gravity, while its horizontal motion is constantly retarded; so that its direction continually approaches to the perpendicular, or a parallel with EF. This resistance of the air is so great as to amount in some cases to twenty or thirty times the weight of the ball itself, insomuch that a ball which in the air ranges only to the distance of one mile, if projected with the same velocity in vacuo would range ten or twenty times that distance.

The determination by theory of the trajectory described by a projectile in the air is, as Dr. Hutton remarks, one of the most difficult problems in dynamics. "Even the solutions of Newton, Bernoulli, Euler, Borda, &c. &c., after the most elaborate investigations, assisted by all the resources of the modern analysis, amount to no more than distant approximations; and are rendered nearly useless, even to the speculative philosopher, from the assumption of a very erroneous law of resistance in the air, and much more so to the practical artillerist, both on that account, and from the very intricate process of calculation which is quite inapplicable to actual service." (*Tracts*, vol. iii.) It may easily be inferred from these remarks that no practical rules can be founded on deductions from pure theory; and that it is necessary to have recourse to trial and experiment in order to obtain even an approximate knowledge of the path of a body projected with so great a velocity as that of a cannon ball.

The first extensive series of accurate experiments on this subject was made by Benjamin Robins, and is described by him in his *New Principles of Gunnery*, published in 1742. In this work, which is one of very great merit and elegance, Mr. Robins has treated very fully of the resistance of the atmosphere, the force of gunpowder, the advantages and defects of different guns, and indeed of almost every thing relating to the flight of military projectiles. Another set of experiments was undertaken by Dr. Hutton at Woolwich, in 1775, of which an account was published in the *Phil. Trans.* for 1778. A second course of experiments was performed by Dr. Hutton in 1783, 1784, and 1785; the principal objects of which were to determine the effect of the length of the gun on the velocity of the ball, the velocities with different charges of powder, the effect of varying the weight of the piece, the penetration of balls into blocks of wood, the ranges

and times of flight, &c. The details of these experiments, which were conducted with great skill and ability, are given in the 2d and 3d volumes of his *Tracts*. Previous to this time a number of experiments similar to those of Robins were made in France by D'Arcy, an account of which is given in the *Memoirs of the Academy* for 1751, and in his *Essai d'une Théorie d'Artillerie*, published in 1760. There is also an extensive series of experiments on the effects of musket balls of different weights, and fired with different charges of gunpowder, by Count Rumford, recorded in the *Phil. Trans.* for 1781, and re-published with additions in 1802. Since the days of Dr. Hutton further experiments with heavy guns appear to have been made from time to time at Woolwich, under the direction of the ordnance department, as there is an account of a very heavy ballistic pendulum, weighing 7408 lbs. avoirdupois, constructed under the care of Dr. Olinthus Gregory in 1815 and 1818, together with some results from experiments on it with a 24-pounder, given in the *Annales de Chimie*, tom. v. and ix., and also in Dupin's *Voyages dans la Grande Bretagne;* but as we are not aware that these results have ever been published in any official form, we know not what credit is to be attached to them. The experiments of Dr. Hutton continue to the present time to afford the best data for the theory of practical gunnery.

There are various methods by which the initial velocity (the principal element in the theory) of military projectiles may be determined. The first is by the *ballistic pendulum*, which consists merely of a heavy block of wood suspended in such a manner that it can swing freely about an axis; into this the ball is fired; and as it is too thick for the ball to pass through it, the whole momentum of the ball is transferred to the block, and the extent of the arc through which it vibrates shows what this momentum has been; whence, as the weights of the block and the ball are known, the velocity with which the latter entered the block may be computed. (BALLISTIC PENDULUM.) Another method of determining the initial velocity of the ball is by means of the recoil of the gun. The principle is, that the explosive force of the powder must communicate equal quantities of motion to the gun and to the ball in opposite directions: consequently, by suspending the gun, loaded with additional weights, in the manner of a pendulum, the extent of its arc of vibration will give the means of estimating the quantity of motion impressed on it; whence the initial velocity of the ball can be computed. Both the above methods were employed by Dr. Hutton: Robins employed the first only. A third method consists in transferring the momentum of the ball to a rotatory machine instead of a pendulum. An ingenious apparatus for this purpose was contrived by Dr. Gregory, but the method has been little used.

The following are the practical conclusions deduced by Dr. Hutton from his experiments: —

1. The velocity is directly as the square root of the weight of the powder, as far as to the charge of about eight ounces; and so it would continue for all charges were the guns of an indefinite length. But as the length of the charge is increased, and bears a more considerable proportion to the length of the bore, the velocit falls the more short after that proportion.

2. That the velocity of the ball increases with the charge to a certain point, which is peculiar to each gun, where it is greatest; and that by farther increasing the charge the velocity gradually diminishes till the bore is quite full of powder.

3. It appears that the velocity continually increases as the gun is longer, though the increase of velocity is very small in respect of the increase in length, the velocities being in a ratio somewhat less than that of the square roots of the length of the bore, but somewhat greater than that of the cube roots of the length, and is indeed nearly in the middle of the ratio between the two.

4. The range increases in a much less ratio than the velocity, and indeed is nearly as the square root of the velocity, the gun and elevation being the same. Very little is gained in the range by a great increase in the length of the gun, the charge being the same; and indeed the range is nearly as the 5th root of the length of the bore, an increase so small as to amount only to about one-seventh part more range for a double length of gun.

5. It appears that the time of the ball's flight is nearly as the range, the gun and elevation being the same.

6. It appears also that there is no sensible difference caused in the velocity or range by varying the weight of the gun, nor by the use of wads, nor by different degrees of ramming, nor by firing the charge of powder in different parts of it.

7. But a great difference in the velocity arises from a small degree of windage. Indeed with the usual established windage only, namely, about 1-20th of the calibre, no less than between 1-3d and 1-4th of the powder escapes and is lost; and as the balls are often smaller than that size, it frequently happens that half the powder is lost by unnecessary windage.

8. It appears that the resisting force of wood to balls fired into it is not constant; and that the depths penetrated by different velocities or charges are nearly as the logarithms of the charges, instead of being as the charges themselves, or, which is the same thing, as the square of the velocity.

9. These, and most other experiments, show that the balls are greatly deflected from the directions they are projected in; so much, indeed, as 300 or 400 yards in a range of a mile, or almost 1-4th of the range, which is nearly a deflection of an angle of 15 degrees. (*Dictionary*, art. "Gunnery.")

Dr. Hutton gives the following table as the results of his experiments with a medium one-pounder gun, the iron ball being nearly two inches in diameter; showing the velocity of the ball, the range, and time of flight, corresponding to different charges, the elevation of the gun being 15 degrees: —

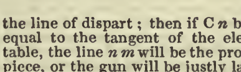
Powder.	Initial Velocity per Second.	Range.	Time of Flight.
Ounces.	Feet.	Feet.	Seconds.
2	860	4100	9
4	1230	5100	12
8	1640	6000	14½
12	1680	6700	15½

In the application of the rules derived from experimental inquiry, it is necessary to take into consideration the effect that is intended to be produced. The power of penetration which a ball possesses is proportional to the square of its velocity; hence, when the object is merely to penetrate, the greatest velocity should be given. Thus in breaching walls the guns are first directed so as to cut grooves in the wall, in order to detach as it were a portion from the rest of the mass. This is done by the penetration of the balls; but the detached portion must then be battered so as to cause it to fall. For this purpose a heavy ball with small velocity is most effectual. In close naval engagements great velocities are less destructive than small ones. The ball, for example, which has just force sufficient to go through a ship's side, generally breaks and splinters the interior surface, and thereby causes far more damage than when it retains a considerable velocity after having passed through; for in the latter case it will only cut a hole without splintering the wood. On this principle the *carronade* (a short species of ordnance fired with a small charge of powder in proportion to the ball) has been introduced into the naval service.

Pointing and elevating Guns. — The art of pointing cannon so as to strike distant objects depends on two things; 1st, on placing the gun in such a position that its axis is in the vertical plane passing through the object aimed at; and 2d, on giving it such an elevation as will counteract the effect of the incurvation of the flight of the ball. When a gun is both pointed and elevated, it is said to be *laid*.

A line drawn from the highest point of the base ring to the highest point of the swell of the muzzle is called the *line of metal*. Now if the line of metal be directed to the object, that line will necessarily be in the same vertical plane with the object; but by reason of the conical shape of the gun, the line of metal has an inclination to the axis, which is called the *dispart*, and in consequence of which the axis will only be in the same vertical plane with the line of metal when the trunnions are perfectly horizontal. If they are not so (and the condition cannot be easily attained or preserved), the shot will be thrown to that side of the object on which the lower trunnion is. This inconvenience is obviated by placing a dispart sight on the muzzle, at a height perpendicularly above its highest point equal to half the difference of the diameters of the muzzle and base ring; for then a line which passes from the highest point in the base ring to the extremity of the dispart thus placed on the muzzle ring will be parallel to the axis, and consequently the shot will not be thrown to the right or left of the object, however much the one trunnion may be lower than the other.

In order to determine the proper elevation to be given to the gun, it is necessary to know the distance of the object fired at. Tables have been constructed from actual practice, showing the angles of elevation which in different guns correspond to different distances; and the angle being found from the table, the proper elevation is given by means of a brass tangent-scale which slides up and down in the breech. Thus suppose C D E F to be the piece, A B its axis, F m half the difference of the diameters of the muzzle ring and base ring set upon the muzzle, so that C m may be the line of dispart; then if C n be set upon the base ring equal to the tangent of the elevation found from the table, the line $n\,m$ will be the proper line for pointing the piece, or the gun will be justly laid when $n\,m$ is directed to the object. In practice the length of C n is found with sufficient accuracy by multiplying the length of the gun in feet by ·21; the product giving C n in inches. This rule is founded on the supposition that the tangent of one



degree of a circle, whose radius is one foot, is equal to the 21-100ths of an inch, which is very near the truth.

The following table (from the *Ency. Brit.*, art. "Gunnery"), constructed from actual practice at Woolwich, shows the elevations corresponding to different ranges with iron ordnance of the kinds therein specified:—

Nature.	Weight of Gun.	Charge.	Elevation.	Range.	Elevation.	Range.	Elevation.	Range.
	Cwt.	*Lbs. Oz.*		*Yds.*		*Yds.*		*Yds.*
42-pr.	58¼	14 0	0·00°	400	1·33°	1100	3·50°	1500
32	55½	10 11	0·25	500	2·00	1200	3·75	1550
24	50	8	0·50	600	2·25	1250	4	1600
18	42	6	0·75	700	2.50	1300	5	1800
12	34	4	1·00	800	2·75	1350	6	1980

(*Robins's Math. Tracts; Hutton's Tracts; Sir Howard Douglas's Naval Gunnery;* Paixhans, *Force et Faiblesse de la France;* and the *United Service Journal* for 1834.—For a very complete theoretical discussion of the experiments hitherto made, the reader may consult a *Mémoire sur la Vitesse initiale des Projectiles*, in the *Journal de l'Ecole Polytechnique*, tom. xv. 1835.)

GU'NNEY. (Bengal.) A coarse sackcloth made in Bengal of the fibres of two species of *corchoron.* Rice, saltpetre, pepper, and other articles exported from Calcutta are packed in bags or sacks made of this material; they also form a considerable article of exportation.

GU'NPOWDER. A compound of about 78 parts of saltpetre, 12 of charcoal, and 10 of sulphur. The ingredients should all be perfectly pure, separately reduced to powder, thoroughly mixed, moistened, and beaten or pressed into a cake; which is afterwards broken up, granulated or corned, dried, and polished by attrition. Coarse powder is less carefully and nicely manufactured. The force of the explosion of gunpowder is the consequence of the sudden and abundant production of gaseous matter expanded by the intense heat resulting from the action of the combustibles upon the nitre. The gases evolved are chiefly carbonic oxide, carbonic acid, nitrogen, and sulphurous acid, and their volume probably exceeds two thousand times the bulk of the powder. Count Rumford's experiments show the immense energy of this astonishing agent as a source of mechanical power (*Phil. Trans.* vol. 87.): 28 grains of gunpowder, confined in a cylindrical space which it just filled, tore asunder a piece of iron which would have resisted a strain of 400,000 lbs. applied at no greater mechanical advantage. With regard to the introduction of gunpowder into warlike operations, Dr. Thomson has the following remarks:—The discoverer of this compound, and the person who first thought of applying it to the purposes of war, are unknown. It is certain, however, that it was used in the fourteenth century. From certain archives quoted by Wiegleb, it appears that cannons were employed in Germany before the year 1372. No traces of it can be found in any European author previously to the thirteenth century; but it seems to have been known to the Chinese long before that period. There is reason to believe that cannons were used in the battle of Cressy, which was fought in 1346. They seem even to have been used three years earlier, at the siege of Algesiras; but before this time they must have been known in Germany, as there is a piece of ordnance at Amberg on which is inscribed the year 1303. Roger Bacon, who died in 1292, knew the properties of gunpowder; but it does not follow that he was acquainted with its application to fire-arms.

GUNPOWDER PLOT. In English History, the celebrated conspiracy of certain disappointed Roman Catholics to destroy the king, James I., and the two Houses of Parliament, by gunpowder, which was detected on the 4th of November, 1605. Its details are among the most popular portions of English history, and too well known to need repetition. But the miraculous exercise of sagacity by which King James is commonly said to have detected the nature of the plot, from the mysterious letter sent to Lord Monteagle, is now perhaps negatived beyond a doubt. It had long been remarked that Salisbury and Carlisle (probably before the scheme between themselves and their royal master was concerted) had claimed for *themselves* the credit of the discovery; and it now appears that Lord Monteagle had been previously rewarded by government for mysterious services, apparently rendered in the capacity of spy: so that it is highly probable that he was acquainted with the design of the malecontents, and that the celebrated letter was an invention, destined to conceal the real mode of discovery. Those who are anxious to study the Roman Catholic version of the story will find it ably detailed in the pages of *Lingard* (vol. vii. ch. 1. 4to ed.). That writer seeks to throw the whole onus of the conspiracy on Catesby, its chief promoter, and to exculpate Father Garnet; but Mr. Jardine (in his *State Trials*), who has fully investigated the subject, is of a different opinion.

GU'NTER'S CHAIN, so called from its reputed inventor, is the chain commonly used for measuring land. It is 66 feet or 4 poles in length, and is divided into 100 links, each of which is joined to the adjacent one by three rings; and the length of each link, including the connecting rings, is 7·92 inches. The advantage of this measure consists in the facility which it affords to numerical calculation. The English acre contains 4840 square yards; and Gunter's chain being 22 yards in length, the square of which is 484, it follows that a *square chain* is exactly the tenth part of an acre. A square chain again contains 10,000 square links, so that 100,000 square links are equal to an acre; consequently, the contents of a field being cast up in square links, it is only necessary to divide by 100,000, or to cut off the last five figures, to obtain the contents expressed in acres.

GUNTER'S LINE. A logarithmic line engraved on scales, sectors, &c., serving to perform the multiplication and division of numbers instrumentally, as a table of logarithms does arithmetically. The numbers are usually drawn on two separate rulers sliding against each other. In rough calculations this line affords considerable facilities.

GUNTER'S QUADRANT. A quadrant of a peculiar kind adapted to the problems of finding the hour of the day, the sun's azimuth, and other common problems of the sphere.

GUNTER'S SCALE, casually called by seamen *the Gunter*, is a large plain scale having various lines of numbers engraved on it, by means of which questions in navigation are resolved with the aid of a pair of compasses. On one side of the scale the natural lines (as the line of chords, the line of sines, tangents, rhombs, &c.) are placed, on the other the corresponding logarithmic ones.

GU'NWALE means, generally, the upper part of the solid workmanship of the vessel's side: the part above this is called the bulwark.

GU'TTA SERENA. *See* AMAUROSIS.

GUTTÆ. In Architecture. *See* DROPS.

GUTTI'FERÆ, or CLUSIACEÆ. A natural order of arborescent, shrubby, and occasionally parasitical Exogens, inhabiting the tropics.

GU'TTUR (Lat. guttur, *a throat*), in Mammalogy, is applied to the whole under surface of the neck.

GU'TTURALS. Letters pronounced by a peculiar effort of the throat. There are no gutturals properly so called in the English language, although the guttural sound may often be heard in some provincial pronunciations of the letter *r*. Nor are there in the pure French or Italian, although they are freqent in the dialects: *e.g.* the letter *c* hard (as in *casa*) has the Tuscan a strong guttural sound. In the Spanish language alone, of those derived from the Latin, gutturals are common. In German, the guttural *ch* is largely used. In the Celtic languages, *gh* and *ch* are also sounded with much variety of guttural intonation.

GUY. A rope used to swing any weight, or to keep steady any heavy body and prevent it from swinging while being hoisted or lowered.

GYMNA'SIARCH. (Gr. γυμνάσιαρχος.) An Athenian officer who had the charge of providing the oil and other necessaries for the gymnasia. This was one of the offices called λειτούργιαι at Athens, the expenses of which were defrayed from the private pocket of the individual on whom they devolved, and who received no salary from the state.

GYMNA'SIUM. (Gr. γυμνάσιον, from γύμνος, *naked.*) Originally a space measured out and covered with sand for the exercise of athletic games. Afterwards, among the classical Greeks, the gymnasia became spacious buildings or institutions for the mental as well as corporeal instruction of youth. They were first built at Lacedæmon, whence they spread through the rest of Greece, &c. into Italy. They did not consist of single edifices, but comprised several buildings and porticoes, used for study and discourse, for baths, anointing rooms, palæstras in which the exercises took place, and for other purposes. Two of the Athenian gymnasia, viz. the Lyceum and Academy, were rendered famous by being the scenes of the lectures of Aristotle and Plato respectively.

The term Gymnasium has descended to modern times. In Germany the higher schools, intended to give immediate preparation for the universities, are termed gymnasia. In Prussia the scholars undergo examination on leaving them: their compositions at this examination are sent to the minister of instruction and ecclesiastical affairs; and they receive testimonials of fitness, No. 1, 2, or 3, according to their degree of proficiency. Persons who have fitted themselves for the universities without passing through the gymnasia are examined by a committee appointed by government, which sits half-yearly for the purpose.

GYMNA'STICS. Under this name were comprised by the ancients all those games and exercises which were performed with the body partly naked (γυμνός); such as wrestling, boxing, running, throwing the quoit, playing

at ball, &c. They were first instituted at Lacedæmon, where they were not confined to men, but were also considered a necessary part of the education of females. In the rest of Greece, where they subsequently spread, they were also held of the highest importance, and as such were conducted under the superintendence of the government. and entered conspicuously into the political schemes of the philosophers. In this respect the Greeks offered a remarkable contrast to their Asiatic neighbours, among whom it was considered a great disgrace even for a man to be seen naked. At Rome gymnastics were principally exercised by the mercenary athletes.

GY'MNODONTS, *Gymnodontes.* (Gr. γυμνος, *naked ;* οδους, *a tooth.*) The name of the family of Plectognathic fishes comprehending those which have the jaws protruding, and covered with a more or less complex layer of dense ivory substance serving the office of teeth.

GYMNO'SOPHISTS. (Gr. γυμνοσοφισται, *naked philosophers.*) A sect of Indian philosophers who lived naked in the woods, whence they derived their name, and submitted to other strange austerities. They believed in the immortality of the soul and its migration into several bodies. They enjoyed great reputation for astronomical and physical science.

There was likewise an African sect of philosophers bearing the same name, who are said to have lived in Æthiopia, near the sources of the Nile, whose habits differed from those of the Indian sect, inasmuch as they lived as anchorites, while the latter congregated in societies.

GYMNO'TUS, or rather *Gymnonotus.* (Gr. γυμνος, *naked*, and νοτος, *the back.*) The name of the genus of electric eels which are found in the fresh waters of South America: they have a median fin extended along the belly, but none on the back. Although to all outward appearance the gymnotus is nearly allied to the eel, yet, were that part of the body cut off which contains the nutrient, respiratory, and generative organs, — all the parts, in fact, which are essential to the existence of the gymnotus as a mere fish, — it would present a short and thick-bodied form, very different from that of the eel. The long electric organs are tacked on, as it were, behind the true fish, and thus give the gymnotus its anguilliform body. The back-bone and muscles are of course coextended with the electric organs for their support and motion; and the air-bladder is continued along the produced electrophorous trunk, to give it convenient specific levity. Two long dorsal nerves are continued from the fifth and eighth cerebral nerves for ordinary sensation and motion. The spinal chord is continued along the vertebral column, for the exclusive supply of the electrical organs. These organs are four in number; two very large above, and two small ones below. The electricity discharged from them decomposes chemical compounds, produces the spark, and magnetizes iron, as does that of the torpedo. But the magnetizing power seems to be relatively weaker, while the benumbing shock communicated to other animals is stronger than in any other electric fish.

GYNÆCE'UM. (Gr. γυναικειον.) In Ancient Architecture, the portion of a Grecian house set apart for the occupation of the female part of the family.

GYNÆCE'UM. In Botany, a term invented by Rœper to denote that organ commonly called the pistillum: it may be understood to signify the female apparatus in plants.

GYNA'NDRIA. (Gr. γυνη, and ανηρ, *a male.*) The name of one of the classes in the sexual system of plants invented by Linnæus. Its character is to have the stamens, style, and stigma consolidated into a body, called a column. The class chiefly consists of the plants now named *Orchidaceous.*

GYNŒCO'CRACY. (Gr. γυνη, and κρατεω, *I govern.*) A term sometimes used to indicate that state in which women are legally permitted to assume the reins of government. It is used by way of contradistinction to the *Salique law*, which precludes the fair sex from the privilege of sovereignty. There are only four states in Europe to which the operation of the Salique law does not extend — England, Russia, Spain, and Portugal.

GY'NOPHORE. (Gr. γυνη, and φερω, *I bear.*) The stalk upon which some ovaria are seated, as in the Passion-flower.

GYNOSTE'MIUM. (Gr. γυνη, and στημων, *a stamen.*) A term invented by Richard to denote the column of an Orchidaceous plant. It is a combination of a filament and a style.

GYPOGE'RANUS. (Gr. γυψ, *a vulture*, and γερανος, *a crane.*) This name was invented by Illiger for a most singular genus of Accipitrine birds, in which the structure of the bird of prey is modified by a lengthening of the legs and neck to adapt the species to combat with and destroy the most poisonous of the serpent tribe. The instincts of the gypogeranus, or secretary bird, as it is termed, correspond with its structure, and it preys principally on serpents; not refusing, however, lizards, or even insects. The bill is shorter than the head, curved nearly from its base, not toothed; the wings are armed with a short, strong, and obtuse spur; the feathers are continued down the long tibia to the tarsal joint, covering the front but not the back part of it; the toes are short, but strong; the anterior ones united by a membrane at the base. Species of the secretary vulture inhabit the Cape, the Gambia coast, and the Philippine Islands. The Cape secretary (*Gypogeranus serpentarius*) lives in pairs, builds on high trees, and runs with considerable swiftness.

GY'PSIES. The history of this strange nation of vagrants has been recently illustrated by the labours of several German writers, particularly Grellman (*Historical Inquiry respecting the Gypsies*, translated into English by Raper, 1787) and Bischoff (*German and Gypsy Dictionary*). Their English name is a corruption of the word "Egyptian:" the French call them Bohemians; but the names by which they are most widely known throughout Europe are, the German *Zigeuner*, Russian *Tzigan*, Italian *Zingaro*, Spanish *Gitano*, Turkish *Chinganeh*, — all apparently varieties of the same distinctive appellation. Their origin has long been a subject of curious but unsuccessful antiquarian research. In western Europe, they made their first appearance early in the fifteenth century, under a leader who styled himself the Duke of Lower Egypt: fortune-telling and thieving were then, as now, their predominant occupations. They were at that time treated as heathens and sorcerers, and the most severe laws were repeatedly enacted against them, but without effect. At present they are found not in Europe only, but in Asia Minor, Egypt, Turkey, &c., forming everywhere a distinct race. In Germany, as well as England, they profess various trades, as itinerant horsedealers, smiths, farriers, &c.; but have never been reclaimed in any number to settled occupations. In England their most ordinary haunts are in the midland and southern counties chiefly, whither they are invited by the abundance of green lanes, downs, forests, or chases. They possess a language of their own; and are apparently destitute of religion, although in most countries professing that of the people among whom they dwell. (See *Marsden on the Language of the Gypsies; Hoyland's Hist. Survey*, 1816; *Quart. Rev.* vol. lv. Mr. George Borrow's *Account of the Gypsies of Spain*, 2 vols. 12mo. 1841, may also be consulted with great advantage.)

GY'PSUM. (Probably derived from γη, *earth*, and εψω, *I concoct.*) Crystals of native sulphate of lime.

GY'RI (Gr. γυρος, *a circle*), in Mammalogy, the annular series of scales in the tails of certain quadrupeds.

GY'RODUS. A fossil fish of the family of *Pycnodonts.* It occurs in the oolite of Baden.

GYRO'GONITES. (Gr. γυρος, and γονος, *seed.*) Bodies found in fresh-water deposits; originally mistaken for small shells, but afterwards ascertained to be the seed-vessels of plants of the genus *Chara.*

GY'ROMANCY. (Gr. γυρος, and μαντεια, *prophecy.*) A species of divination performed by drawing a ring or circle and walking round it.

H.

H. An aspirate of the guttural kind, used in all modern and in most ancient languages. The claims of *h* to be regarded as a letter have been denied by many grammarians; and certainly, when it is remembered that the sound of this letter is produced by a mere emission of the breath, without any conformation of the organs of speech, this opinion would seem well founded. There are others, however, who insist that there is no feature in the sound or qualities of this letter which it does not possess in common with some other consonants, and consequently any attempt to invalidate its claim to the distinction militates equally against them. The figure H was used by the Greeks to signify the aspirate, until about the 5th century before Christ. After that time it was gradually abandoned in Greek writing, while its use was still preserved by the Latins. In the former language it was superseded by the small mark called the *spiritus asper* (ʽ), which was placed above the letter to which the aspirated sound was to be given. The various interchanges of which this letter is susceptible will be found in the *Penny Cyclo.* The chief of these is the substitution, in Latin, of the letter *s* for the aspirate of the Greeks; as *sub* for ὑπο, *sal* for ἁλς, *sex* for ἑξ, *septem* for ἑπτα, *serpo* for ἑρπω, &c. In English, this letter is frequently dropped altogether in pronunciation: in German, it is sounded only at the beginning of words; and wherever it otherwise occurs, it has the effect of lengthening the vowel after which it is placed, as in *sēhnen*, *wāhrheit.* In Latin, many words are written indifferently with or without this letter; as aruspex, haruspex, onustus, honustus, &c. As an abbreviation, *h* was used by the Latins for homo, hæres, and hora; and as a numeral it expressed 200.

HAA'RKIES. (German.) Capillary pyrites in very delicate acicular crystals. The term is also applied by the German mineralogists to a native sulphuret of nickel.

HA'BEAS CO'RPUS. (Lat.) In Law, the title of a writ, of which there are several kinds. *Habeas corpus ad respondendum*, is to remove a prisoner, confined by the process of an inferior court, in order to charge him with a new action in a court above. *Habeas corpus ad subjiciendum* is a high prerogative writ, directed to a person detaining another, and commanding him to produce the body of the prisoner. This is the writ which, by stat. 31 C. 2. c. 2., must be granted on application of any party committed and charged with any crime except treason or felony; or, if charged with those crimes, having been acquitted or not tried on the second term or session after his commitment.

HABE'RE FA'CIAS POSSE'SSIO'NEM. (Lat.) In Law, a judicial writ, which lies where one hath recovered a term of years in action of ejectment to put him into possession. *Habere facias seisinam*, a similar writ to give seisin of a freehold estate recovered by ejectment or other action.

HA'CKLE. A board set with sharp iron spikes for combing or pulling out hemp.

HA'DES. (Gr. ᾅδης; also ἀΐδης, which is said to be derived from ἀ and εἴδω, *I see; invisible.*) In Classical Mythology, the abode of the dead. According to Hesiod the mortals of the brazen age were the first who descended to Hades. (See especially the 11th book of the *Odyssey;* Hesiod, Εργα και Ἡμεραι; *Æneid*, book vi.; Warburton's Dissertation on the latter; Heyne, *Excursus* 8. ad loc.; *Spence's Polymetis*, Dial. 16.) Hades was also an appellation of the god Pluto; in which sense alone, it is said, Hesiod uses it.

HA'DING. In Mining, the direction of a slip or *fault*. The deviation from the vertical of a mineral vein is called its *hade*.

HADJ. (Arab.) The Mohammedan pilgrimage to Mecca and Medina: whence Hadji, a pilgrim, or one who has performed this pilgrimage; Hedjaz, the Holy Land, where these cities are situated. By far the most authentic description of it is that of Burkhardt, who performed it, in the guise of a Mohammedan, in 1814. It is fixed to a particular lunar month, and consequently takes place in every season of the year. It was a custom long anterior to the establishment of Islamism, when the famous "black stone" of the Caaba at Mecca was an object of idolatrous veneration. Every year a black silk stuff is now sent by the sultan to cover the Caaba. There are usually five or six caravans; from Syria, Egypt, Barbary, the East, and the North. In 1814, the number of pilgrims was about 70,000, and this was considered small. The pilgrims go through several ceremonies at Mecca, of which the principal are the *towaf*, or procession round the Caaba, and drinking of the well Zemzem; they then proceed to the summit of Mount Ararat; and lastly to Medina, the place of the prophet's burial. (*Burkhardt's Travels in Arabia*, 1829; *Quart. Rev.* vol. xlii.)

HÆMATE'MESIS. (Gr. αἱμα, *blood*, and εμειν, *to vomit.*) Vomiting of blood from the stomach, generally preceded by weight and uneasiness about the region of the stomach, and unaccompanied by cough and the other symptoms of *hæmoptysis*.

HÆ'MATITE. (Gr. αἱμα.) Native oxide of iron: its streak and powder are blood-red.

HÆMATOCE'LE. (Gr. αἱμα, and κηλη, *a tumour.*) A tumour arising from extravasated blood.

HÆMATOSI'NE. (Gr. αἱμα.) The red colouring matter of the blood.

HÆMATO'XYLINE. The colouring principle of the wood of the *Hæmatoxylon campechianum*, or logwood.

HÆMATU'RIA. (Gr. αἱμα, and ουρον, *urine.*) A discharge of bloody urine.

HÆMODORA'CEÆ. (Hæmodorum, one of the genera.) A natural order of Endogens principally inhabiting New Holland. They differ from *Amaryllidaceæ* in their flowers and equitant leaves; from *Iridaceæ* in their stamens, and in the anthers bursting inwards. They are curious, but not useful or beautiful plants; except in the case of *Anigoranthus*, a genus containing some striking herbaceous species.

HÆMO'PTYSIS. (Gr. αἱμα, *blood*, and πτυω, *I spit.*) The coughing up of blood, sometimes produced by fulness of the blood-vessels of the lungs, or by the rupture of blood-vessels as a consequence of ulceration. It is distinguished from blood coming from the stomach by the comparative smallness of its quantity, and by its usual florid colour: the latter is usually blackened by the acid, and often mixed with the contents of the stomach. The age at which this disease commonly shows itself is from fifteen to five-and-twenty, and it is sometimes brought on by violent exercise or a fit of coughing. It is not very uncommon as a symptom of suppression of some natural evacuation; and when unattended by symptoms of consumption and constitutional cough, and occurring in persons otherwise strong and healthy, it is often not dangerous: when it occurs in some fevers, and in inflammation, it may even be a favourable symptom. Bleeding, aperients, acids, diaphoretics, nauseants, and occasionally the exhibition of small doses of sugar of lead and of styptic astringents, are the remedies usually resorted to.

HÆ'MORRHAGE. (Gr. αἱμα, and ῥαγη, *rent.*) A bleeding or flow of blood. This may arise from two causes: either a full state of the vessels, or *plethora*, when it has been called *active hæmorrhage;* or from a debilitated state of the vessels, or of the system generally, when it is called *passive hæmorrhage*. When hæmorrhage occurs from either of these causes, it usually requires methods of treatment adapted to the particular case. Where hæmorrhage is the consequence of wounds, the bleeding vessels must be secured by ligature; or where this cannot be done, styptic applications are applied.

HÆ'MORRHOIDS. (Gr. αἱμα, and ῥεω, *I flow.*) Tumours of the veins of the rectum, constituting the disease commonly called piles.

HÆRE'SIARCH. (Gr. αἱρεσις, *heresy;* αρχω, *I begin.*) In Ecclesiastical History, the founder of an heretical sect. *See* HERESY.

HÆRESI'MACHÆ. (Gr. αἱρεσις, and μαχομαι, *I fight.*) In Ecclesiastical History, those who have written controversial works against heresies. Of the earliest Christian writers of this description, who wrote chiefly against Basilides, Marcion, and the Montanists, we have only fragments remaining. The first complete treatise of this description extant is that of Irenæus against the Gnostics (A. D. 180).

HAG, or HAG-FISH. A vernacular name for a species of Cyclostomous fish called *Myxine glutinosa* and *Gastrobranchus cæcus* by ichthyologists.

HAGIO'GRAPHA. (Gr. ἁγιος, *holy*, and γραφη, *writing or Scripture.*) The Holy Scriptures. The term is also applied to histories or legends respecting the lives and actions of the saints. See *Riddle's Christian Antiquities*, 1839, p. 394., as to that particular class of the Hebrew Scriptures which were termed by the Jews *Hagiographa*.

HAIL. (Germ. hagel.) A well-known meteor, which occurs chiefly in spring and summer, not unfrequently accompanied with thunder. It is formed of rain or atmospheric vapours congealed by cold in the upper regions of the atmosphere, and falling to the ground in small roundish masses, or *hailstones*. On examining attentively the interior structure of hailstones they are usually found to contain an opaque nucleus of a spongy or porous texture, resembling hardened snow, surrounded by a layer of ice of greater or less transparency. Sometimes several transparent layers are distinguishable, and sometimes the layers are alternately transparent and opaque. Hailstones have also been observed having a radiating structure. Their form is exceedingly various; in general it is roundish, but sometimes pyramidal, angular, or even thin and flat, with irregular surfaces. The usual size of hailstones is about a quarter of an inch in diameter; but they are frequently of much greater magnitude, and instances are on record in which the dimensions would appear incredible if they were not attested by observers of known character. Halley relates that on the 9th of April, 1697, there fell in Flintshire hailstones which weighed 5 ounces. On the 4th of May, 1697, Robert Taylor, in Hertfordshire, observed hailstones which measured 14 inches in circumference; that is, about 4 inches in diameter. Parent, on the 15th of May, 1703, found them at Iliers as large as his fist. On the 11th of July, 1753, at Toul, some were collected by Montignot measuring 3 inches in diameter. Volta affirms that on the night of the 19th of August, 1787, in a hail storm which ravaged the city of Como and its environs, some of the stones were found to weigh 9 ounces. In the terrible hail storm which traversed the whole of France and the Netherlands on the 13th of July, 1788, M. Tessier relates that hailstones were picked up which weighed 8 ounces. And Dr. Noggerath informs us that on the 7th of May, 1822, hailstones fell at Bonn, weighing from 12 to 13 ounces. From these relations we may form some idea of the destruction occasioned by a severe hail storm in a cultivated country.

Of the different circumstances accompanying a fall of hail, the following are the most remarkable: — Hail usually precedes storms of rain, sometimes accompanies them; but never, or very rarely, follows them, especially if the rain is of any duration. The time of its continuance is always very short, generally only a few minutes, and very seldom so long as a quarter of an hour. The quantity of ice which falls from the clouds in so short a time is prodigious, the ground being sometimes covered with it to the depth of several inches. The clouds from which hail is precipitated appear to be of very considerable extent and depth, inasmuch as they produce a great obscurity. It has been remarked that they have a peculiar grey or reddish colour, and that their lower surfaces present enormous protuberances, while their edges exhibit deep and numerous indentations. Hail is always accompanied with electric phenomena.

Various hypotheses have been proposed to explain the physical cause of hail, and the phenomena by which it

is accompanied. The theory requires the solution of two questions: first, how the cold which causes the congelation of the aqueous particles is produced? and, secondly, how a hailstone, after attaining a sufficient size to fall through the air by its own weight, remains suspended a sufficient length of time to acquire a volume of twelve or fifteen inches in circumference? But both these questions are attended with very considerable difficulty; and after all that has been written on the subject, the theory of hail is still involved in great obscurity.

The first hypothesis we shall mention is that of the celebrated Volta. In order to solve the first question, Volta supposed that the solar rays which impinge on the upper surface of a dense cloud are almost entirely absorbed, whence a very rapid evaporation results, and that this evaporation produces a sufficient degree of cold to freeze water. To this part of the theory it has, however, been objected that the evaporation of a liquid through the effect of heat can only become more rapid in consequence of the liquid acquiring a higher temperature; in other words, that a liquid cannot, at the same time, receive an additional quantity of caloric and have its temperature diminished without the intervention of some other cause. For instance, let two sheets of paper be moistened to the same degree, and one of them be exposed to the sun's rays, and the other placed in the shade; it will soon be seen that the one on which the sun's rays fall dries more quickly: its evaporation is greater; but, at the same time, it becomes warmer than the other, whereas, according to Volta's argument, it ought to become colder.

Volta's solution of the second question is ingenious, but not satisfactory. Admitting the nuclei of the hailstones to be formed, and that there exists a sufficient degree of cold to produce their enlargement by freezing the aqueous vapours, he supposes two large strata of clouds, charged with opposite electricities, to be disposed the one over the other; in which case the hailstones, still very small, falling on the lower stratum would experience the two following effects:—In the first place, they would penetrate the stratum on which they fall to some extent, and be covered with a new coating of ice. In the second place, they would acquire the same electricity as the cloud, and consequently be repelled by it; while at the same time they would be attracted by the upper stratum, on account of its preserving the opposite electricity. And the electric attraction of the cloud being supposed greater than the force of gravity, the hailstones would thus pass from the lower to the upper stratum, where analogous effects would take place, and whence, consequently, they would be repelled to the lower stratum. Thus they would be kept passing alternately from the one stratum to the other, until at length, either becoming too heavy, or the clouds losing their electricity, or being carried by the wind to too great a distance from each other, the cause which kept the hailstones suspended in the atmosphere becomes inadequate to support them, and they are precipitated to the ground.

It is obvious that the accuracy of this theory cannot be proved by any direct experiment; and doubts have even been raised whether the existence of electric forces sufficient to move masses of ice of the size which hailstones are frequently found to have, in the manner the theory supposes, be really possible. The following, which is much simpler, seems adequate to the effects. We may suppose the cold necessary for the formation of hail to be produced by the wind; and that when the hailstones are formed they are also carried along through the atmosphere by currents of wind in a direction very oblique to the horizon, by which means they may be kept suspended a sufficient length of time to acquire the dimensions they possess by congealing the particles of humid vapour with which they successively come in contact. Thus the same cause, namely, the wind, determines the production and the enlargement of hailstones; and the electricity with which the phenomenon is always accompanied is only the effect of the passage of the particles of water from the liquid to the solid state.

For further information on this subject the reader is referred to an interesting article by Arago in the *Annuaire Presentée au Roi* for 1829; also Pouillet's *Elémens de Physique*, tome ii.

HAIR. (Germ. haar.) The characteristic covering of the Mammiferous class of animals. It consists of slender more or less elongated horny filaments, secreted by a matrix, consisting of a conical gland or bulb, and a capsule, which is situated in the mesh-work of the corium, or true skin. The hairs pass out through canals in the corium, which are lined by a thin layer of cuticle adherent to the base of the hair: the straightness or curl of the hair depends on the form of the canal through which it passes. Spines, bristles, fur, and wool are all modifications of hair, having the same chemical composition, mode of formation, and general structure.

In the spines of the porcupine the bulb secretes a fluted pith, and the capsule invests it with a horny sheath, the transparency of which allows the ridges of the central part to be seen. In the spines of the hedgehog, the spine-like whiskers of the walrus, and the bristles of the hog, the twofold structure of the hair is very conspicuous; but in the finer kind of hair, as of the human head and beard, the central pith can only be demonstrated in fine transverse sections viewed with a microscope. Some kinds of hair, as of the human head, the mane and tail of the horse, are perennial, and grow continuously by a persistent activity of the formative capsule and pulp; other kinds, as the ordinary hair of the horse, cow, and deer, are annual, and the coat is shed at particular seasons. In the deer the horns are shed contemporaneously with the deciduous hair.

Many quadrupeds, especially those of cold climates, have two kinds of hair: a long and coarse kind, forming their visible external covering; and a shorter, finer, and more abundant kind, which lies close to the skin, and called "fur." It is one of the processes in the arts to remove the coarse hair, and leave the fur attached to the dried skin, as in the preparation of seal-skin, &c. The peculiar characteristic of wool, and that on which its valuable qualities chiefly depend, is the serrated character of its surface, arising from its structure, which consists of a series or succession of inverted cones, the base of each being directed from the root of the woolly fibre, and receiving the apex of the succeeding cone. It results from this structure that the pressure to which the workman subjects the wool in moving it backwards and forwards, brings the fibres together and multiplies their points of contact. The agitation gives to each hair a progressive motion towards the root, and the serrations of one hair fix themselves on those of another hair which happens to have its root turned in the opposite direction, and the mass at length assumes that compact form which is termed "felted" wool. The microscope has likewise demonstrated various other remarkable modifications in the form of the hair in different quadrupeds. In the mole, *e. g.*, each hair is alternately constricted and expanded from its root to its apex, whereby it readily assumes any position, and lies flat and smooth, either towards the head when the little burrower is retrograding in his subterraneous galleries, or in the contrary direction when moving forwards. The organization of the hair is such as to allow of its undergoing certain changes when once formed, according to the state of health and general condition of the rest of the frame, and even to be affected by loss of colour in consequence of violent mental emotions in the human subject. Some of the lower animals, as the Alpine hare, are subject to periodical change of colour of their fur, by which it is made to harmonize with the prevailing hue of the ground which they habitually traverse.

The chemical properties of hair were first pointed out by Mr. Hatchett, in his paper in the *Phil. Trans.* for 1800. It chiefly consists of an indurated albumen, and when boiled with water it yields a portion of gelatine. Soft flexible hair, which easily loses its curl, is that which is most gelatinous. Vauquelin discovered two kinds of oil in hair: the one colourless, and in all hair; the other coloured, and imparting the peculiar tint to hair. Black hair also contains iron and sulphur.

HAIRS. In Botany, minute, transparent, filiform processes, composed of cellular tissue more or less elongated and arranged in a single row. They spring from the surface of plants, appear always to have a circulating system, and probably act both as absorbents of moisture and protectors of the surface in which they grow. Many sorts are distinguished by phytotomists, the principal of which are the secreting or glandular, which are composed of cellules that are visibly distended either at the apex or base into receptacles of fluid; and the lymphatic, which consist of tissue tapering gradually from the base to the apex.

HA'LBERT. A word of uncertain derivation, applied to an *offensive* weapon, which consists of a shaft five feet long, with a steel head, partly in the form of a crescent. This weapon was formerly in considerable use in the army, and indeed gave its name to a body of men called halberdiers; but it is now rarely to be met with except in some boroughs in Scotland, where it is used by the civic officers who attend the magistrates in processions, and on other public occasions.

HA'LCYON. *See* ALCEDO.

HALCYON DAYS. A name given by the ancients to the seven days that precede and follow the winter solstice, from the circumstance of the halcyon or alcedo selecting that period for incubation. While this process was going on, the weather was generally remarkable for its calmness; and hence the expression has passed into a proverb, signifying days of peace and tranquillity. This circumstance is beautifully alluded to by Ovid in the following lines:—

> Perque dies placidos hiberno tempore septem
> Incubat Halcyone pendentibus æquore nidis.
> Tum via tuta maris: ventos custodit et arcet
> Æolus egressu: præstatque nepotibus æquor.

HALCYONI'DÆ. (Gr. *ἀλκυων, a king-fisher.*) The family of Fissirostral birds, having the kingfisher as the

type. (*Halcyon*, from ἁλκυων, itself is derived from Gr. ἁλς, and κυω, *I procreate*, because the halcyons build their nest on the sea-shore.)

HALIO'TIDÆ. (Gr. ἁλς, *the sea*, and ους, *the ear*.) A family of Gastropods, having as its type the genus *Haliotis*, or the sea-ear

HALL. (Sax. heal.) In Architecture, properly a large room for the transaction of public business; also a manor house where courts are held for the admission of tenants and other manorial business. It is perhaps a term improperly applied, as now, to the entrance of a dwelling-house, though not so to a servants' hall. At Oxford an unendowed college is styled a *hall;* but at Cambridge the term is used indiscriminately for *college*, whether endowed or not.

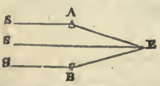
HALLELU'JAH. (Heb. *praise ye the Lord.*) A well-known doxology, derived from the Old Testament. It was used, among the early Christians, at Easter, and during the interval from thence to Whitsuntide. (*Greg. Epist.* ix. Ep. 12.) See *Riddle's Christian Antiquities*, p. 334.

HA'LLIARDS, *Haulyards*. Ropes by which yards, sails, and signals are hoisted.

HA'LO. (Lat. halo.) In Meteorology, a luminous circle or ring, usually coloured, surrounding the sun or moon under certain conditions of the atmosphere. Of such rings there are two kinds, which appear to depend on essentially different physical causes. The first are of small dimensions, their diameters being between 5° and 12°; and generally three or more concentric rings appear together, differently coloured, and presenting appearances similar to the optical phenomena of the rings of thin plates. These are usually called *coronæ;* and they appear either when a small quantity of aqueous vapour is diffused through the atmosphere, or when light fleecy clouds pass over the sun or moon. The second kind consists usually of a single luminous ring, but of much larger dimensions, the diameter being about 45°. It is to the meteors of this second kind that the term *halo* is usually appropriated.

The apparent diameters of halos of the second kind have frequently been measured, and are always found to subtend at the eye of the observer an angle of between 44° and 46°. The lunar halo is simply a white luminous circle, without colour, excepting a pale red, which sometimes fringes the interior edge of the circle. But the colours of the halos about the sun, though not so bright as those of the rainbow, are, however, marked with sufficient distinctness. The red occupies the interior part of the luminous circle; the indigo and violet the outer part, and shade away by insensible degrees till they are blended with the general colour of the sky. In some circumstances a second halo is observed concentric with the former, but of much larger extent, its apparent diameter being about 90°. The colours of this secondary halo are faint and pale, and its luminousness much inferior to that of the inner halo. The halos are very frequently attended by a horizontal white circle, with brighter spots, or *parhelia*, near their intersections with this circle, and with portions of inverted arches of various curvatures. *See* PARHELIA.

Various causes have been assigned for the origin of halos; but the most probable is that of Mariotte, who supposes the phenomenon to arise from the refraction of light in passing through small transparent and prismatic crystals of ice floating in the higher regions of the atmosphere. Water assumes, in congealing, a great variety of crystalline forms, among which are frequently found crystals whose faces are inclined to each other in an angle of 60°; thus forming prisms of ice of which the refracting angle is 60°. These prisms are turned in all possible directions, and consequently the sun's rays fall on their faces at all different inclinations. But in certain positions of the prism with respect to the incident light, the rays which traverse it suffer a minimum deviation, which happens when the refracted ray makes an isosceles triangle with the two sides of the prism. The path of the ray in the interior of the crystal in this case makes an angle of 60° with the face of the crystal, or an angle of 30° with the perpendicular to that face. This last angle is the angle of refraction; and it is known by experiment that in the case of ice, the angle of refraction being 30°, the angle of incidence is 41°; hence the ray falls on the crystal at an angle of $90° - 41° = 49°$; consequently the deviation of the ray from its original direction is $60° - 49° = 11°$. On escaping from the crystal, the ray suffers a second flexure of the same amount; and the total deviation from its first direction is now $2 \times 11° = 22°$, which is the semidiameter of the halo. It follows, therefore, that the parallel rays



S A, S B, from the sun falling on such prisms at A and B at angles of incidence equal to 41°, will be refracted into the directions A E and B E, which make angles A E S and B E S equal to 22°; and an eye situated at the intersection E will see a luminous circle of which the apparent diameter, or angle A E B, is about 44°. With respect to the secondary or external halo, whose diameter is about 90°, it may be attributed, says Dr. Young (*Lectures*, vol. i. p. 444.), either to two successive refractions through different prisms, or with greater probability, as Mr. Cavendish suggested, to the refraction of the rectangular terminations of the prisms.

This theory explains the order in which the colours are disposed. The ratio of the refraction of the violet ray being greater than that of the red ray, the former will suffer a greater deviation, and consequently the violet band of the halo will have a greater diameter than the red. Supposing this theory to be correct, the condition necessary for the appearance of halos is the existence of particles of ice in the upper regions of the atmosphere. The appearance of a halo, therefore, furnishes information respecting the temperature of the air at great altitudes above the earth.

The formation of *coronæ*, or the small halos so frequently seen round the sun and moon in fine weather, is ascribed by Fraunhofer and Sir John Leslie, not to the *refraction* but to the *deflection* of light in passing by the small watery globules súspended in the atmosphere. If a piece of tinfoil punctured with the point of a needle be held close to the eye, the sun will appear through it surrounded with a halo very near his disk, but spreading more in proportion as the hole is contracted. Supposing that an aqueous globule of equal dimensions would produce an equal deflection, the magnitude of the globules might thus be inferred from the diameter of the halo. When the halo approaches nearest to the luminous body, the largest globules are floating, and therefore the atmosphere is surcharged with humidity; whence the justness of the remark that a dense halo close to the moon portends rain. For a full exposition of the theory of halos and other similar meteors, the reader is referred to a Memoir by Fraunhofer in *Schumacher's Astronomische Abhandlungen*, 3 tes. heft; or to the article "Hof," in *Gehler's Physicalisches Worterbuch*. See also *Newton's Optics; Smith's Optics;* Pouillet, *Elémens de Physique; Cabinet Cycl.*, art. "Optics;" *Ency. Brit.*, art. "Meteorology."

HA'LOGENS. (Gr. ἁλς, *salt.*) Substances which by combination with metals produce saline compounds; such as chlorine, iodine, bromine, fluorine, which are simple halogens; and cyanogen, which is a compound halogen.

HA'LOID (Gr. ἁλς.) This term is applied to a class of chemical combinations composed of two bi-elementary compounds, one or both of which are analogous in composition to sea salt. The principal groups consist of double chlorides, iodides, fluorides, and cyanurets.

HALTI'CA. A genus embracing numerous species of small and often minute Coleopterous insects, of the family *Galerucidæ*, and section *Tetramera*. These insects have the femoral joints of the hind legs thick and strong, and are consequently good leapers. The native species are smaller than the foreign ones, but are more noxious than might be expected from their diminutive size. The notorious turnip-fly, or rather turnip-flea (*Chrysomela nemorum* of Linnæus), is a species of the present genus.

HAMADRY'ADS. (Gr. ἁμα, *together*, and δρυς, *an oak.*) Certain nymphs or inferior deities supposed by the Greek and Roman poets to preside over woods and forests, and, as their name implied, to live and die with the particular trees to which they were attached.

HA'MITES. (Lat. hamus, *a hook.*) A genus of extinct Cephalopods, which inhabited chambered shells, losing their spiral form soon after their commencement and then continued for a considerable extent with a single bend upon themselves like a hook. The *Hamites* are found in the greensand formation in England.

HA'MLET. (Diminutive of the Saxon ham, *home or house.*) A small village. In Law, a hamlet is a portion of a village or parish, and synonymous with *vill.*

HA'MMER BEAM. (Sax. hamer.) In Architecture, an horizontal piece of timber from or near, but above, the foot of a rafter, the object of which is to act as a tie.

HA'MMOCK. The sailors' bed. An oblong piece of hempen cloth: at each end are fastened several small lines, meeting in a grummet or iron ring; these form the *clues*. The whole, having a mattrass and pillow, &c. placed in it, is hoisted up into its place by small ropes called *laniards*, between two battens or screws in the beams of the deck over head, about nine feet distant asunder. The hammock is a very agreeable bed, especially in cold weather; but some little practice is requisite at first in getting in and out successfully. During the day the hammocks, lashed up tight in the form of caterpillars, are stowed in the nettings along the upper edge of the bulwark.

HA'MSTER. A Rodent quadruped, somewhat larger than a rat, common in all the sandy regions that extend from the north of Germany to Siberia; extremely noxious from its fertility and great destruction of grain, but an object of interest on account of the economic instincts which conduce to its preservation and support. The hamster excavates a complicated burrow, consisting of different apartments for rearing the young, hibernating, and storing up winter food. An old hamster will often

amass a hundred pounds' worth of grain, and fill up a subterraneous magazine which is sometimes seven feet deep. To effect this hoard nature has provided the hamster with a means of transport in two large cheek-pouches, which, during its incursion among cultivated grounds, it crams full of grain, beans, or peas, and empties on its return to its hole by pressing the two fore-paws against the cheeks. The hamster, however, is not wholly dependent on its winter store for existence. During the inclement months, when the frost becomes severe, animation is in great measure suspended, and the need of nourishment abrogated: respiration ceases, the animal heat falls, sensation is benumbed, and a kind of vegetative life is maintained by a slow circulation of dark or venous blood through both sides of the heart. When the returning warmth of spring stimulates the organic machinery to its wonted activity, the awakened hamster finds in the nourishment which it has providently stored up the means of supplying the consequent waste, and of maintaining its vital energies. They are thus enabled to commence the business of procreation in April, and the female rears a litter of six or eight twice or thrice every year. In about three weeks the young are able to provide for themselves, and are driven from the holes of the parents. The hamster (*Mus cricetus* of Linnæus) is the type of the genus *Cricetus* of Cuvier, characterized by the short tail and cheek-pouches. The teeth nearly resemble those of the rat.

HAMULA'RIA. (Lat. hamus, *a hook.*) A species of worm said to have been found in the bronchial glands of a person who died of typhus.

HA'NAPER OFFICE. A common law office in the court of Chancery, in which writs were anciently kept in small separate wicker baskets (hampers, *hanaperia*), of which specimens may still be seen among the records at the Chapter House. Writs relating to the subject were deposited there; those concerning the crown in the Petty or Little Bag, whence another office of the same court is denominated.

HA'NDLING. (From *hand.*) In Painting, management of the pencil by touch. Handling should be bold, with freedom, firmness, and spirit.

HA'NDSPIKE. A wooden lever employed on board a ship in working the windlass and capstan, one end of which is squared to fit the holes in the capstan head and in the barrel of the windlass.

HANK. In Spinning, the name given to two or more skeins of yarn, silk or cotton, when tied together. When single, they are called skeins.

HANKS. Rings of ash or iron, by which sails are confined to their stays, upon which they traverse while setting or hauling down.

HANNO'S PERIPLUS. *See* PERIPLUS.

HANSA, HANSE, or HANSEATIC LEAGUE. In European History, a celebrated confederacy of cities on the coasts of the Baltic, and in the adjoining countries. The first league was formed in 1239, between Hamburg, Minden, and many other towns, to which Lübeck soon afterwards acceded: it was for the purpose of mutual defence against foreign potentates, especially the Danish king Waldemar, as well as the neighbouring nobles of Germany. The league rapidly spread, and comprehended, at one period, eighty-five cities, divided into four provinces. It had four chief foreign depôts: at London, Bruges, Novgorod, and Bergen. In the 14th and 15th centuries the league became of high political importance, and made war and peace as an independent sovereign power, but it was never recognized by the German empire. Its decay was gradual, and, owing to the increased protection given to commerce by the princes of the several states in which these cities were situated, rendering the alliance for mutual defence unnecessary. The name is derived from Hansa, an old Teutonic word signifying *league*.

HA'QUEBUT. A word of French origin, or more probably a corruption of the term *arquebuse* or *harquebuse*, with which it is identified in meaning. *See* ARQUEBUSE.

HA'RBOUR, has been defined to be a piece of water communicating with the sea, or with a navigable river or lake, having depth sufficient to float ships of considerable burden, where there is convenient anchorage, and where ships may lie, load, and unload, screened from the winds and beyond the reach of the tide. For a view of the utility of harbours in general, and the qualities essential in good harbours, with a notice of the principal harbours in this and other countries, see *The Commercial Dictionary*.

HARD BODIES, in Natural Philosophy, are such as resist any pressure or percussion whatever: in opposition to soft bodies, the parts of which readily yield to pressure, and do not recover themselves; and to elastic bodies, the parts of which also yield to pressure or impact, but presently recover themselves when the disturbing force ceases to act.

HA'RDNESS. In Physics, that quality of bodies in virtue of which their particles resist the action of any external force tending to alter their relative positions, or to impart to them any motion in respect of each other. Newton supposes the primary particles of all bodies to be perfectly hard, and not capable of being broken or divided by any power in nature; but we are still too little acquainted with the constitution of matter to determine with any certainty the conditions of the elementary particles which render bodies hard, brittle, elastic, &c.

HARDNESS. In Mineralogy. Minerals may occasionally be distinguished and identified by their relative degrees of hardness; to specify which various scales have been suggested, among which that of Mohs is perhaps the most simple. According to it the relative degrees of hardness are expressed in numbers, referring to the following standard substances, which are easily obtained in a state of purity, or crystallized; namely,

1. Talc.	6. Adularia (Felspar).
2. Rock-salt.	7. Rock-crystal.
3. Calc-spar.	8. Topaz.
4. Fluor-spar.	9. Corundum.
5. Apatite.	10. Diamond.

Any mineral which neither scratches nor is scratched by any one of the above substances is said to possess the hardness expressed by the attached number. Thus if a mineral neither scratches nor is scratched by calcareous spar, its hardness is represented by 3; if it scratches felspar and not rock-crystal, its hardness is stated to be between 6 and 7.

HA'RDWARE, is used to signify every kind of goods manufactured from metals, comprising iron, brass, steel, and copper articles of all descriptions. The hardware manufacture is one of the most important carried on in Great Britain. Its principal seats are Birmingham and Sheffield, which furnish immense quantities of knives, razors, scissors, gilt and plated ware, fire-arms, &c., both for home consumption and exportation. The total aggregate value of the joint hardware manufactures of England and Scotland may be estimated (*Statistics of British Empire*, i.) at not less than 17,500,000*l.* a-year, affording direct employment in the various departments of the trade to 360,000 persons.

HARE. *See* LAGOMYS and LEPUS.

HARELIP. A fissure or perpendicular division of the lip, so named from its supposed resemblance to the upper lip of a hare. Children are frequently born with this malformation, and sometimes it is the consequence of accidents or wounds. It most usually affects the upper lip; and is not only a serious deformity, but may prevent the infant from sucking and cause impediment of speech. The cleft is sometimes double. This malformation admits of partial or entire relief by a surgical operation, which should generally not be performed upon very young infants, in consequence of the risk of convulsions.

HA'REM. (Turk.) The name given to those apartments in the houses of the East which are appropriated to the exclusive use of the females of the family. *See* SERAGLIO.

HA'RLEQUIN, in the Italian Comedy, is the name given to the person who performs a part something similar to that of the clown or merry-andrew of the mountebank stages in our own country. Harlequin forms also one of the standing characters in the grotesque entertainment of the pantomime. The word is of doubtful etymology. *See* PANTOMIME.

HARMONICA. *See* MUSICAL GLASSES.

HARMO'NICAL I'NTERVAL. In Music, the same as *Concord*, which see.

HARMO'NICAL PROGRESSION. A series of numbers, such that any three consecutive terms are in harmonical proportion. The principal property of this progression is, that the reciprocals of the terms form an arithmetical progression; and, conversely, the reciprocals of an arithmetical form an harmonical progression.

HARMO'NICAL PROPORTION, called also *Musical Proportion*. Three numbers are said to be in harmonical proportion when the first is to the third as the difference of the first and second is to the difference of the second and third: thus, 2, 3, and 6, are in harmonical proportion, because 2 : 6 : : 1 : 3. And four numbers are said to be in harmonical proportion when the first is to the fourth as the difference of the first and second is to the difference of the third and fourth: thus 9, 12, 16, and 24, form an harmonical proportion; for 9 : 24 : : 3 : 8.

HARMO'NICS. In Music, the doctrine of the differences and proportions of sounds with respect to acute and grave. This doctrine was by the ancients divided into seven parts; viz. of sounds, of intervals, of system, of the genera, of the tones or modes, of mutation, and of melopæia.

HARMO'NIC TRIAD. In Music, the chord of a note consisting of a third and perfect fifth, or, in other words, the common chord.

HA'RMONITES. A sect of enthusiasts, founded by one Rapp, in Wurtemberg, about 1780; who, finding no toleration there, emigrated with his followers to America. He first settled in Pennsylvania, and afterwards removed to Indiana; but about 1822 again returned to the former state, and established himself near Pittsburg. Many details will be found on the subject of his sect in books of

travels in America, but few written with any knowledge of the subject beyond mere external observation. It is a mistake to suppose that his followers lived in celibacy; but they regarded marriage as no part of the discipline of their church, and treated it as a civil act only.

HA'RMONY. (Gr. ἁρμονία.) In Music, an agreeable combination of sounds heard at the same instant. As a continued succession of single musical sounds produces melody, so does a continued combination of several together in succession produce harmony.

HA'RMONY OF THE SCRIPTURES, GOSPELS, &c. The correspondence of the several writers of different parts of the Scriptures in their respective narratives, or statements of doctrine. The earliest Harmony of the Gospels was composed by Tatian, in the second century, with the title *Diatessaron*. Among many other valuable works of this description may be mentioned Osiander, *Harm. Evangelica*; Cartwright, *Harm. Ev. Commentario illustrata*, 1647; Le Clerc, *Harmonie Ev.*, Amst. fol. 1699; *Macknight's Harmony of the Four Gospels*, 1756.

HA'RMONY, PRE-ESTA'BLISHED. A hypothesis invented by Leibnitz, to explain the correspondence between the course of our sensations and the series of changes actually going on in the universe, of which, according to that philosopher and many others, we have no direct knowledge. (*See* PERCEPTION.) This hypothesis is connected, in the Leibnitzian system, with the doctrine of monads, — certain spiritual powers or substances, one of which constitutes the principle of vitality and consciousness in every living being. Each of these is, in its degree, a mirror, in which the changes going on in the universe are reflected with greater or less fidelity. But between simple substances, such as spirit and matter, soul and body, no real reciprocal action can take place. The Author of the universe has consequently so ordained that the series of changes going on in any particular conscious monad, corresponds precisely to those of the monads in contiguity to which it is placed. Hence arises our belief that mind is acted on by matter, and vice versa; a belief which leads to no practical errors in virtue solely of this pre-established harmony. (See *Tennemann. Grundr.* p. 339.; *Brown's Lectures*, 31.)

HARMO'STES. (Gr. ἁρμοστής; from ἁρμόζω, *I fit.*) In Ancient History, a Spartan magistrate, called also sometimes *sophronistes* (σωφρονιστής, *moderator*), who was appointed to superintend a conquered state. It is conjectured from *Thucyd.* iv. 53. that the office was annual. Other Greek states which made conquests afterwards borrowed the name. Xenophon speaks of Theban *harmostæ* in Achæa. (*Hist.* l. vii.)

HA'RMOTOME. (Gr. ἁρμος, *a joint*, and τεμνω, *I divide.*) A mineral chiefly from Andreasberg, in the Hartz, the crystals of which often intersect each other, and are easily separable. It is also called cross-stone, or staurolite. *See* CROSS-STONE.

HA'RMUS. (Gr. ἁρμος.) In Ancient Architecture, a tile used for covering the joint between two common tiles.

HARP. (Germ. harfe.) A musical stringed instrument of great antiquity, in which the strings are stretched on a triangularly-formed frame, and pinched, or rather pulled, by the fingers, to set them in vibration and produce the different sounds. The harp is represented on many Egyptian monuments; and though it is usually admitted to be of Eastern origin, it seems doubtful whether it was known to the Greeks and Romans in any shape analogous to its present form. Of late years this instrument has been much improved by pedals and other devices; but it is still imperfect, and more suited to the chamber than the orchestra.

HA'RPA. (Ger. harfe.) A genus of Pectinibranchiate Mollusks, dismembered from the Linnæan *Buccinum*, and remarkable for the elegance of form and beauty of the markings of the shell: this is traversed by longitudinal compressed sinuous parallel ribs, which may be compared to the strings of a harp.

HA'RPALUS. (Gr. ἁρπαλεος, *rapid.*) A genus of predaceous Coleopterans, and the type of a family (*Harpalidæ*), which is one of the principal divisions of the Linnæan genus *Carabus*.

The *Harpalidæ* are divided into three principal sections, characterized by modifications of the anterior *tarsi* of the male.

1. *Harpalinæ*, having the four anterior tarsi of the males dilated.
2. *Feroninæ*, having the two anterior tarsi dilated, and the joints heart-shaped.
3. *Patellimana*, having the two anterior tarsi of the males dilated; the joints being square or rounded.

Each of these sections contains numerous subgenera, of which *Harpalus proper* contains many British species. *Harpalus ruficornis* is perhaps the most common; it exceeds half an inch in length, with opaque black elytra and body, and red legs and antennæ.

HA'RPAX. A genus of fossil shells, oblong and somewhat triangular, the hinge being formed by two projecting teeth. (*Parkinson.*)

HA'RPIES. (Gr. Ἅρπυιαι; from ἁρπάω, *I seize.*) In Greek Mythology, the daughters of Pontus and Terra, according to some mythologists. Hesiod makes them three in number, with the names Iris, Aello, Ocypete. They were a species of furies or monsters, winged and clawed like birds. They are best known from the celebrated description in *Virgil* (*Æn.* iii. 211. &c.). See a memoir in vol. xii. of the *Mem. de l'Ac. des Inscr.* for the varying mythological accounts respecting them.

HARPOO'N. A well-known spear for striking the whale.

HA'RPSICHORD. (Fr.) A keyed musical instrument, in which the sounds are produced by means of small vertical sticks, called jacks, upon which the keys act as levers. In the jacks are inserted short pieces of quill; these, upon passing the strings, set them in vibration. This instrument is now little used; indeed, we believe, in the present day none are manufactured.

HARPY'IA. (Gr. Ἅρπυια, *Harpy.*) This term has been applied both to a genus of Raptorial birds and to a genus of Lepidopterous insects.

HA'RROW. In Agriculture, a rectangular frame with a number of spikes inserted in it on one side. This frame, when dragged over ploughed land, breaks the furrow slices into small pieces, for the purpose of preparing the land for seed in some cases, and for covering the seed in others. The most common form of the frame of the harrow is rectangular, and the usual material employed is wood, with the spikes of iron; but in some cases both the frame and the spikes are of wood, and in others both are of iron. Occasionally the frame is a circle of iron; and the spikes are inserted in it, at such distances that when the frame is drawn along in a straight line the spikes, or tines as they are technically termed, pass through every part of the soil traversed by the frame or harrow. In the common kinds of harrows the spikes are inserted at right angles to the frame; but in the improved forms they are inserted at an oblique angle, or pointing forwards, by which means the harrow is drawn much more easily through the soil. The best implement of this description at present in use is Finlayson's harrow. This implement, by means of a long lever, can be regulated to such a nicety as to stir the soil to the depth of only one or two inches, for the purpose of covering grass or clover seeds; or it can be pressed into it of such a depth as to serve, in the case of stubble lands, instead of ploughing. Wilkie's harrow and Kirkwood's harrow can be used for similar purposes. They differ nothing from Finlayson's in principle; but being on a smaller scale can be worked with fewer horses than Finlayson's, which commonly requires four or six.

HA'RROWING. The process of drawing a harrow through the soil for the purpose of reducing it to a level, of covering seed, or of turning up weeds in ploughed ground, or moss in grass lands. In agriculture the harrow is drawn by horses or oxen; and in market-gardening, where a light harrow is sometimes employed, by men. In either case the more rapid the motion of the harrow, up to a certain point, the more efficient will be its operation. For meadow lands, the object of harrowing is to disperse the little heaps of earth raised during winter and early spring by moles and worms; and for this purpose the harrows in some parts of the country are turned upside down; while in others, as in Middlesex, thorn branches are tucked into a frame resembling a harrow, and dragged over the surface for the purpose of effecting the same object. This is called a bush harrow.

HA'RTSHORN, SPIRIT OF. An impure solution of carbonate of ammonia, obtained by the destructive distillation of harts' horn or any kind of bone. An impure solid carbonate of ammonia, called *salt of hartshorn*, is formed at the same time.

HA'RVEST. (Germ. herbst.) In Agriculture, the period at which any crop is reaped. The term is more commonly applied to the crops of corn or hay, though it might, with propriety, be applied to the potatoe crops, or to hops and other field products.

HA'RVESTING. The operation of pulling, cutting, rooting up, or gathering field crops, and drying or otherwise preparing them for being stored up for winter use. The first harvest which occurs in Britain and similar climates is that of the forage grasses, or other plants made into hay; the next is the harvest of cereal grasses, or of corn crops; and the third the potatoe harvest, or harvest of root crops, such as potatoes, carrots, turnips, mangel wurzel, &c. There is also the harvest of occasional crops; such as that of rape-seed, turnip-seed, dyers' wood, hemp, flax, and various other articles.

HASTA'TI. (Lat. hasta, *a spear.*) One of the three grand divisions of the Roman infantry, so called because they were armed with spears. It consisted of young men in the flower of life, who were always drawn up in the first line of battle. The other two divisions were called Principes and Triarii; to which, in the first Punic war, was added another, called Velites, or *light* troops, from volare, *to fly*.

HATCH, is the covering of a hatchway. In very bad weather the hatches are battened down, to keep the water which comes in upon the decks from getting below.

HA'TCHETINE. A fusible wax-like substance, found occasionally in nodules of ironstone: named after Mr. Hatchett. It is usually placed by mineralogists amongst bitumens.

HATCHMENT. In Heraldry, a species of *achievement* or funereal escutcheon, suspended in front of a house to mark the decease of one of its inmates. These escutcheons are always drawn up with heraldic precision; so that those acquainted with the science of heraldry can discover at a glance, from the form and accompaniments of the field and the colour of the ground of the hatchment, the sex, position, and rank of the deceased. *See* HERALDRY, ESCUTCHEON.

HA'TCHWAY. A large opening in a ship's deck for communicating with the decks below, the hold, &c.: there are the fore, main, and after hatchways.

HAT. (Germ. hut.) What is usually called a *beaver* hat is made of a variety of furs, chiefly those of the hare and rabbit, mingled with wool, and in the best hats a proportion of beaver's fur; but the latter is altogether omitted in common *stuff* hats. The furs are mixed; the long hair is picked out; and they are then placed on a hurdle, which is shaken and made to vibrate by being struck with a bow-string; in this way the dust is shaken out, and the fibres are to a certain extent interwoven. (*See* FELT.) A quantity of this mass of fur sufficient for one hat is called a *bat* or *capade* (see *Ure's Dictionary*, art. "Hatmaking"): it is pressed, kneaded, and at length moulded so as to form a kind of conical cap, the irregularities or small fibres of the different furs entangling with each other so as to keep the whole adherent. The cap is then dipped into warm water acidulated by sulphuric acid, and wrought by the hands for several hours, by which it is thickened or fulled; the knots are picked out of it, fresh felt here and there added, and the beaver ultimately applied; the hat is then shaped, water-proofed by a lac varnish, tied upon a block, dyed, stiffened by the application of a solution of glue, steamed, brushed, and ironed; the brim is then trimmed, and it is ready for lining and binding.

Silk hats have a foundation of woollen felt, similar to those which are covered by beaver, upon which a silk plush is afterwards applied.

Various processes have lately been suggested, and some of them carried into effect, for the purpose of improving this manufacture. Several of these are described and figured in *Ure's Dictionary*, but their extension and introduction have hitherto been successfully opposed by the journeymen hatters, "among whom," says Dr. Ure, "there exists an organized combination, by which the masters throughout the kingdom are held in a state of complete servitude." "The public of a free country," he adds, "ought to counteract this disgraceful state of things by renouncing the wear of stuff hats, a branch of the business entirely under the control of this despotic union, and betake themselves to the use of silk hats, which from recent improvements in their fabric and dyeing are not a whit inferior to the beaver hats in comfort, appearance, or durability, while they may be had of the best quality for one fourth part of their price."

HA'TTEMISTS. An ecclesiastical sect in Holland, so called from Pontian von Hattem, a minister in Zealand: nearly allied to the Verschorists. They arose in the latter part of the 17th century. They appear to have denied the *expiatory* sacrifice of Christ. It is added, that they denied the corruption of human nature, and the difference between moral good and evil. (*Mosheim*, Transl., ed. 1826, v. 386.)

HAU'BERK. (Ital. usbergo.) A piece of armour, supposed to be of German origin, common in the chain-mail, or rather ringed mail, of the twelfth century; being a jacket or tunic, with wide sleeves reaching a little below the elbow, the hood being of one piece with it. The hauberk of ringed mail ceased to be worn about the reign of Henry III., when the oriental chain-mail, properly so called, came into fashion for a short period.

In France only persons possessed of a certain estate, called *un fief de hauber*, were permitted to wear a hauberk, which was the armour of a knight; esquires might only wear a simple coat of mail, without the hood and hose.

HAUGH. A Scotch term, applied to lands which in England would be called meadow or pasture.

HAUL. The sea term for pulling upon a rope directly.—*To haul the wind*, to bring the ship to sail close by the wind after running in some other direction.

HAUPT TON. (Ger. *head note.*) In Music, that note on which the mark *tr.* is placed, when a shake is indicated; the secondary or superior note being called the *hülfston.*

HA'USTELLATES, *Haustellata.* (Lat. haustellum, *a sucker.*) A name of a grand section of insects, including all those which in the perfect state have the oral apparatus adapted for suction.

HAUTBOIS. *See* OBOE.

HAÜYNE. A blue mineral in small granular or spherical masses, generally found in basalt or lava. Named after Haüy, the celebrated French mineralogist.

HA'VEN. (Germ. hafen.) The same as *harbour*, which see.

HAWK. *See* FALCO.

HAW'KERS, PEDLARS, and PETTY CHAPMEN. In Law, persons travelling from town to town with goods and merchandize for the purpose of sale. They are required to take out licences under 50 G. 3. c. 41. Wholesale traders are exempt from the provisions of this act, as are also licensed auctioneers going from town to town.

HAWKING. *See* FALCONRY.

HAWK-MOTH. *See* SPHINX.

HAWSE. The part of the bows close to the cables. The cables pass through the *hawse holes*, which are made in the timbers and in the *hawse piece* outside. When the ship has two anchors down, and the cables diverge from each other, the hawse is said to be *clear*, when crossed by the ship turning half round, there is a *cross* in the hawse. Another cross makes an *elbow;* then a *round turn:* in the last two cases the hawse is said to be *foul.* The process of disengaging the cables is called *clearing hawse.* The danger of a foul hawse is, that if it comes on to blow the cables cannot be veered from their friction against each other.

Freshening hawse is veering out a little cable to expose a new surface to the friction in the hawse hole, or across the cutwater.

Athwart hawse implies across the bows of a vessel at anchor.

HAWSER. A large rope or small cable.

HA'YMAKING. The operation of cutting down, drying, and preparing forage grasses and other forage plants for being stacked for winter use. The plants are mown down at the time when they are supposed to contain diffused throughout the whole plant a maximum of nutritious juices, viz. when they are in full flower. Dry weather, and if possible that in which sunshine prevails, is chosen for this operation; and the mown material is spread out, and turned over two or three times in the course of the same day in which it is cut. In the evening it is put into small heaps. In the morning of the second day these heaps are spread out, and turned over two or three times; and in the evening they are formed into heaps somewhat larger than they were the day before. If the weather has been remarkably warm and dry, these heaps, in the course of the third day, are carted away and made into a stack; but if the weather has been indifferent, the process of opening out the heaps and exposing them to the sun is repeated on the third day, and stack-making is not commenced till the fourth. A great deal might be said on the subject of haymaking; but it would be altogether unsuitable in a work of this nature. Suffice it to state, that the grand object in making hay is to preserve the colour and natural juices of the herbage, which is best done by continually turning it so as never to expose the same surface for any length of time to the direct influence of the sun. In stacking the hay the object is to preserve this green colour, and at the same time induce a slight degree of fermentation, which has the effect of rendering the fibres of the plants which compose the hay more tender, and changing a part of the parenchymous matter into sugar, on the same principle as is effected by malting barley. This sweet taste renders the hay more palatable to horses. The best directions for haymaking will be found in *Middleton's Agricultural Survey of Middlesex.*

HA'Y-WARD. (Fr. haie, *hedge.*) An officer anciently appointed in the lord's court to take care of the cattle of a manor, and prevent them from injuring the hedges or fences.

HEAD. The fore extremity of a ship. It generally means the cutwater, which is adorned with a figure. *By the head*, implies that the ship's head is depressed in the water. *Head sails, head yards*, are the sails and yards in the fore part of the ship.

HE'ADACH. This is a common symptom in various diseases; it frequently occurs both in full and in debilitated habits, and also in persons who are otherwise healthy. One form of headach consists in a degree of torpor and of confusion, with a dull pain over the whole head, dimness of sight, and inability to attend to anything requiring thought or fixed attention. Sometimes it is referable to disordered stomach or bowels, but it also comes on without any such assignable cause. These headachs are relieved by nervous stimulants, such especially as camphor, ether, and ammonia. A cup of strong coffee or of green tea often acts like a charm; and if the pain prevents rest, a small dose of opium is sometimes necessary, with perfect rest and quiet. Some very troublesome cases are relieved by cold applications to the temples and head, others by snuff and nasal stimulants. There is a peculiar form of headach which consists of throbbing and pain of one particular part, or sometimes over one side of the head; it lasts an hour or two and then goes off, and returns again at stated intervals. This is called *hemicranium*, or *intermitting headach*, and for

its permanent cure often requires bark or sulphate of quinia: blisters behind the ears are also of service. In bilious or sick headach, emetics and purges are required. Obstinate headachs are not unfrequently got rid of by change of air, scene, and occupation; especially where they are the result of too intense intellectual application.

HEA'DBOROUGH. (Sax. borg, *pledge*.) The chief of the ten *pledges* in frankpledge (*see* FRANKPLEDGE); also styled borsholder, tythingman, &c.

HEA'DERS. In Architecture, bricks or stones with their heads or short faces in front.

HEADING COURSES. In Architecture, those courses which consist entirely of headers.

HEA'DLAND. In Geography, a term nearly synonymous with cape, mull, or promontory; which see.

HEADLAND, or HEAD RIDGE, in Agriculture, is a ridge or border, commonly ten or twelve feet broad, which is continued round a field in some cases, and which in others is only formed at the two opposite sides, for the purpose of affording space for the horses to turn on while ploughing.

HEALDS. The harness for guiding the warp threads in a loom.

HEA'RING TRU'MPET. An instrument for concentrating sound, and conveying it to the ear. It is generally a short bent tube, wide at the one end where the sound enters, and narrow at the other where the ear is applied. The principle on which it acts is the reflection of sound at an angle equal to that at which it strikes a smooth surface; and accordingly the form of the instrument ought to be so regulated that the whole of the vibrations are collected into a focus at the smaller end. But it is not necessary that the form which theory points out should be very accurately observed; the principal advantage is gained by confining the advancing sound by a continual reflection, and preventing it from spreading laterally and being dissipated.

HEART. (Germ. herz.) The human heart is a hollow muscular organ of a somewhat conical shape, the broad part of which is called its base, and the smaller end its apex. Its base is placed upon the right of the bodies of the vertebræ, and its apex obliquely to the sixth rib on the left. Internally it is divided into a *right and left ventricle;* the former anterior, and the latter almost posterior, in consequence of the oblique manner in which it is placed. Its inferior surface rests upon the diaphragm. Attached to the base of the heart are two *auricles*, so called from their resemblance in shape to the ear of an animal: they are muscular sacs. In the right auricle are four apertures; two of the venæ cavæ, one of the coronary vein, and one an opening into the right ventricle. In the left auricle there are five apertures; namely, one into the left ventricle, and those of the four pulmonary veins. Each ventricle has two orifices; one from the auricle by which the blood enters, and another into the artery by which it passes out. They are supplied with valves; those at the arterial openings being called, from their form, *semilunar valves;* those at the orifice of the right auricle *tricuspid*, and those at the orifice of the left auricle *mitral*. The valve at the termination of the vena cava inferior, just within the auricle, is called the *valve of Eustachius*. The cavities are lined with a strong smooth membrane. The *pulmonary artery* arises from the right ventricle, and conveys venous blood to the lungs, where having been changed into arterial blood by the action of the air, it returns by the *pulmonary veins*, which terminate in the left auricle; the venæ cavæ, which bring back the mass of venous blood from all parts of the body, terminating in the right auricle. The circle, therefore, which the blood takes is this: — It is returned from the various parts of the body by the venæ cavæ into the right auricle, whence it is forced into the right ventricle, and then through the lungs; whence it returns into the left auricle, and from it into the left ventricle; and thence, by the aorta, through the general arterial circulation. The substance of the heart is supplied by nerves and vessels of its own, which are called *coronary vessels;* the coronary arteries branch off from the aorta, and the coronary veins return their blood into the right auricle. The nerves are branches of the eighth and great intercostal pairs.

HEART WHEEL. The name given to a well-known mechanical contrivance for converting a circular motion into an alternating rectilinear one, common in cotton mills. It is an ellipse turned either on an axle, or by means of a winch and handle on one of its foci, or its centre, on whose edge a moveable point or circle presses; the latter receives an alternating motion from the circumference of the ellipse, which in its revolution presses it to different distances from the centre of motion. The practical disadvantages of this contrivance are the inequality of pressure and of moving force which will be required at different parts of the rotation of the ellipse, and the consequent wearing of some parts of it faster than others. (*Gregory's Mechanics*, vol. ii.)

HEART WOOD. In Botany, the English term for duramen. It is the central part of the trunk of a tree hardened by the deposition in its tissue of various secretions, which clog up the passages and forbid the passage of any thing through them.

HEAT. This term has been applied both to the sensation experienced on touching a hot body, and to the cause of that sensation: in the latter sense it is synonymous with the term caloric. The cause of the phenomena of heat is unknown; but they are supposed to depend upon the presence of a highly attenuated, imponderable, and subtile form of matter, the particles of which repel each other, but are attracted by other bodies. The escape of heat through space is called the *radiation* of heat, and its communication by contact *conduction*. The term *specific heat* is applied to the quantity of thermometric heat required to raise different substances to the same temperature. Thus experiments prove that the quantity of heat which will raise olive oil two degrees will only raise water one degree; hence a pound of water at 212° may be said to contain twice as much heat, or to have twice the capacity for heat that belongs to oil: or the specific heat of water being = 1, that of oil is 0·5. When heat changes the state or form of bodies a large quantity disappears, and remains in them so long as they retain one form. To heat in this state of combination, and inappreciable by the thermometer, the term *latent heat* or *caloric of fluidity* has been applied. *See* EXPANSION, EVAPORATION, &c.

HEATH, or HEATHER. In a general sense the term *heath* is applied to waste land in which the prevailing plants consist of one or more of the common species of heath — *Calluna* and *Erica*. (*Calluna vulgaris*, Sal. The *Erica communis* of Linnæus.) This plant covers many hundreds of acres in the Highlands of Scotland, in Ireland, and in similar climates on the Continent. It attains, in many places, the height of three or four feet; and is used for thatching houses, making besoms, and for a variety of other purposes. The tender tops form a substitute for mattresses in Highland cottages; and they are also eaten green and in a dried state by horses, cattle, and sheep, in countries where the grasses and clovers do not begin to grow till late in the spring.

HEAVE, in nautical phrase, to employ force to move great weights by the lever, &c.; as *to heave up* the anchor by the capstan or windlass; *to heave down* the ship, or pull her over on one side to get at a leak; also *to heave taught* (tight), or turn the capstan till the rope or chain applied to it becomes tight.

HEAVEN, the Celestial Sphere, or Firmament, or Sky, in Astronomy, denotes the spaces in which the celestial bodies are placed, or through which they apparently perform their diurnal revolutions. Aristotle and his disciples believed the heavens to be composed of incorruptible elements, incapable of destruction or of any change whatever; and this opinion long continued to exercise a baneful influence on the progress of astronomy, as it led to the consequence that the celestial bodies are altogether of a different nature from the earth, and have nothing in common with our planet. It was finally overthrown by the discoveries and reasoning of Galileo. The term *heaven* is also frequently used to denote the orb or sphere in which a celestial body appears to move; and hence the ancient astronomers assumed the existence of as many heavens as they observed different and apparently independent motions. They supposed the various heavens to be solid, because they could not otherwise sustain the bodies placed in them; and spherical, because perfect motion must be performed in a circle which is formed by the section of a sphere; and crystalline, because the different bodies are visible, though their orbs include one another. The first heaven was that of the Moon, the second of Venus, the third of Mercury, the fourth of the Sun, the fifth of Mars, the sixth of Jupiter, and the seventh of Saturn. The eighth, which is that of the fixed stars, was called particularly the firmament. Ptolemy added a ninth, which was the *Primum Mobile*. All these reveries have been exploded by the discovery of the true system of the world, and the laws of the planetary motions.

HEA'VY SPAR. Native sulphate of baryta. This is a common mineral in many mining districts. It occurs in several crystalline forms, of which the cleavage is a right rhomboidal prism; it also occurs fibrous, radiated, and stalactitic. Some beautiful specimens of the latter variety have been found in Derbyshire of a brown colour. The crystals are usually white, or nearly colourless. The specific gravity of sulphate of baryta is 4·1 to 4·6. It consists of 77 baryta, 40 sulphuric acid, its equivalent being 117. It enters into the composition of some kinds of pottery, but its chief consumption is in the adulteration of white lead.

HE'BE (Gr. Ἥβη), in Grecian Mythology, was the goddess of youth, whose office it was to hand round the nectar at the banquets of the gods. She was the daughter of Jupiter and Juno.

HE'CATE. (Gr. Ἑκάτη). In Mythology, a Grecian goddess, daughter of the Titan Perses and Asteria. She presided over popular assemblies, war, the administra-

tion of justice, and the rearing of children. There is a good deal of obscurity attached to this goddess, who is often confounded with Artemis or Diana, and Proserpine; whence she is sometimes considered the patroness of magic and the infernal regions. She was called the triple goddess, and was supposed to wander along the earth at night. Statues were set up to her in market places, and especially at cross roads.

HE'CATOMB. (Gr. ἑκατόμβη.) Properly a sacrifice of a hundred oxen; but the word is often used to signify a large sacrifice of any kind of victims.

HECATO'NPEDON. (Gr. ἑκατον, *a hundred*, and πους, *a foot*.) In Ancient Architecture, any temple of the length of one hundred feet.

HECATO'NSTYLON. (Gr. ἑκατον, and στυλος, *a column*.) In Ancient Architecture, a building having a hundred columns.

HECKLE. (Germ. heckel.) An instrument used in separating the fibres of flax and placing them in parallel tresses.

HE'CTIC FEVER. (Gr. ἕξις, *habit*.) A constitutional fever, attended by debility, a small quick pulse, paleness, loss of appetite, excessive perspiration, and emaciation. It generally affects more or less of an intermittent character; but the exacerbations and remissions are irregular, and the sweating stage is not followed by that relief which it usually announces in other febrile attacks. It is often symptomatic of some particular disease, and requires to be treated accordingly. Where this is not the case, or where it merely seems an attendant on general debility, a course of sarsaparilla and a milk diet are often very beneficial; but where this remedy induces perspiration and nauseates, a great deal of management is required in carrying it on for a sufficient length of time to prove of service.

HEDGE. A living wall formed of woody plants, sown or planted in a line, and cut or clipped in such a manner as to form a compact mass of any degree of width and height that may be required for the purpose of shelter, separation, or defence. The fences most generally used in agriculture are made of the white thorn (*Cratægus oxyacantha*, Lin.), because it has spiny branches, and forms a strong defence against cattle. Fences for the purposes of shelter and separation are chiefly used in gardening, and for the most part are formed of evergreen shrubs, such as the holly, yew, box, &c.; or sub-evergreens, such as the privet; of flowering shrubs, such as the *Cydonia japonica*; or of deciduous shrubs or trees with persistent leaves, such as the hornbeam and beech. In the management of hedges of every description an important point is to keep them thick, and impervious to wind or animals near the ground; for which purpose the section of the hedge requires to be made broader at the base than at the top, in order that the exterior leaves in every part of the hedge may enjoy in an equal degree the influence of light, air, and perpendicular rains.

HE'DGEHOG. *See* Erinaceus.

HEEL. The after extremity of the ship's keel: also the foot of a mast. — *To heel over*, to incline to one side.

HE'GIRA. In Chronology, the era used by the Mohammedans in the computation of time. The epoch or first day of this celebrated era, so extensively employed in the East, corresponds to Friday the 16th day of July in the year 622 of the Christian era. It is a problem of some importance to convert dates expressed by the Mohammedan computation into the corresponding dates of our calendar; for effecting this it is necessary to be acquainted with the form of the Mohammedan year.

This year is strictly lunar; and the civil months are adjusted to the lunar months by means of a cycle of 30 years, containing 19 common years of 354 days, and 11 intercalary years of 355 days; the cycle thus containing 10,631 days, or 29 Julian years and 39 days. Each year is divided into 12 months, containing alternately 30 and 29 days, excepting that the last month of the intercalary year contains also 30 days. The intercalary years are the 2d, 5th, 7th, 10th, 13th, 16th, 18th, 21st, 24th, 26th, and 29th of the cycle. The names of the Mohammedan months, with the number of days in each, are as follow: —

	Days.		Days.
Moharem	30	Shaban	29
Saphar	29	Ramadan	30
Rabiu I.	30	Shawall	29
Rabiu II.	29	Dhu'l Kadah	30
Jomadhi I	30	Dhu'l Hajah	29
Jomadhi II.	29	——— in intercalary years	30
Regeb	30		

Such are the chronological elements by means of which Mohammedan dates are reduced to the Christian era. The rule by which the reduction may be accomplished is as follows: —

1. Divide the number of years (of the Hegira) elapsed by 30; the quotient will be the number of cycles, and the remainder the number of years elapsed since the beginning of the current cycle. Call the quotient A, and the remainder B, and let x be the number of intercalary years in B; then the number of days that have elapsed from the commencement of the Hegira to the beginning of the year in which the date occurs is given by this formula,

$$10631\ A + 354\ B + x;$$

for 10,631 is the number of days in the cycle, and 354 the number of days in the common lunar year. To the sum obtained by this formula add the days since the beginning of the current year, and the result is the number of days from the commencement of the Hegira to the given date.

2. To the number of days from the commencement of the Hegira to the given date add the number of days between the commencement of our era and the Hegira, and the sum is the number of days from the first of our era to the given date. The number of days from the beginning of our era to the Hegira, or to the 16th of July, 622, is 227,016.

3. Having now found the number of days from the Incarnation to the given date, it only remains to convert the sum into Julian years. For this purpose divide by 1461 (the number of days in the Julian intercalary period), and call the quotient C. Divide the remainder by 365, and call the quotient D, and the remainder of this last division y. Then 4 C + D is the number of Julian years elapsed since the beginning of the Christian era, and y is the number of days that have elapsed of the current year. This gives the date in Old Style. To reduce it to the Gregorian Style, it is only necessary to add 11 days. (See art. "Chronology," in the *Encyclopedia Britannica*.)

HEIGHT. In Geometry, the same as *altitude*, which see.

HEI'GHTEN. (From *height*.) In Painting, a verb signifying to make prominent by means of touches of light or brilliant colours, as contrasted with the shadows.

HEIGHTS, MEASUREMENT OF. The determination of the relative altitudes of points on the earth's surface is of equal importance in physical geography as the determination of their latitudes and longitudes. There are three different methods by which the operation is usually effected. When it is required to determine not only the height of one point or station relatively to another, but the relative heights of a number of points above a common horizontal plane (as for tracing the line of a canal), recourse is had to the operation of levelling. The second method is to observe the angle of elevation or depression of one station as seen from another, and to compute, from the observation and from the distance of the two stations, the difference of altitude by the rules of trigonometry. The third method, and the most important, as being, generally speaking, the most applicable, is to deduce, by means of the known physical properties of the atmosphere, the differences of vertical height from the observed differences of atmospheric pressure as indicated by the barometer. To this method we shall here confine our attention.

Pascal, who first explained the true cause of the suspension of the mercurial column by referring it to the pressure of the atmosphere, and established the fact of the pressure by his celebrated experiment on the Puy de Dôme, was also the first to suggest the application of the barometer to the measurement of mountains; but as the constitution of the atmosphere and the laws of gaseous bodies were in that age entirely unknown, the numerous attempts which were made to estimate heights in this manner, soon after the introduction of the instrument, had very little success. The first step towards the introduction of a correct theory was the discovery by Mariotte that the elastic force of air (which is the same as the pressure) is exactly proportional to its density; — an important relation, which is true of all the gases and vapours, and goes by the name of Mariotte's law. Dr. Halley next discovered the remarkable relation which connects the density of the atmosphere with the altitude, and proved that the densities decrease in a geometrical progression when the altitudes increase in an arithmetical one. Dr. Halley likewise supposed that the observations might be affected by differences of temperature; and he roughly estimated the variation to amount to a fifteenth part between winter and summer.

De Luc was the first who gave precision to barometrical measurements by taking into account the influence of heat in expanding the air; and by substituting the mercurial for the spirit thermometer, he rendered the determination of temperatures, on which the method so mainly depends, a matter of much greater certainty than it had formerly been. He also investigated the dilatation of air at different temperatures, and gave a formula for the computation of barometrical measurements, which was adapted to the English system of measures by Dr. Maskelyne, and used (with some alterations in the values of the coefficients) by Sir George Shuckburgh and by General Roy in the determination of the altitudes of many of the principal mountains in Britain.

Laplace, in the *Mécanique Céleste*, has given a formula which embraces all the different circumstances on which the solution of the problem depends, and enables us to compute their influence numerically, when the constants

to be found from observation have been accurately determined. Among these are the ellipticity of the earth, the relative densities of air and mercury at a given temperature, their expansion by heat, and the variation of the elastic force of atmospheric air (composed of a mixture of dry gases and watery vapour) corresponding to a given thermometric change. In the present state of our knowledge, some doubt still remains on several of these points; but they are all known with sufficient approximation to render the barometer a most valuable instrument for geodetical purposes. It not only gives the relative altitudes, above the general level, of places however distant at which simultaneous observations are made, but even enables us to assign the height of any station on the earth at which the *mean* height of the barometer is ascertained. We now proceed to give the formula by which the height is computed from the observations.

The temperatures being expressed in degrees of the centigrade scale, let us assume

ϖ = the atmospheric pressure at temperature zero,
D = density of atmospheric air at temperature zero,
θ = the temperature in degrees,
α = ·00375, the dilatation of air for 1° of increased temperature,
$k = \dfrac{\varpi}{D}$, the ratio of the pressure to the density.

If the pressure remains constant, and we suppose that while the temperature changes from 0 to θ any volume V of air becomes V′, and its density D becomes D′, then $V' = V(1 + \alpha\theta)$; and therefore, the densities being inversely as the volumes, $D' = \dfrac{D}{1 + \alpha\theta}$.

Let us next suppose the pressure to vary while the temperature θ remains constant, and that D′ becomes ϱ when ϖ becomes p; then, by the law of Mariotte, $\varpi : p :: D' : \varrho$. Substituting for D′ its above value, and observing that $\varpi = k\,D$, this proportion gives

$$p = k\,\varrho\,(1 + \alpha\theta) \ldots\ldots (1.)$$

This formula holds good for all the gases and vapours, and for their mixtures, as well as for air.

To form the differential equation of the equilibrium of the atmospheric column at any altitude z above the surface, suppose a column of air whose base is 1 to be divided into thin horizontal slices; then the difference of the pressures on the under and on the upper surface of any slice will be equal to the weight of the slice. Let, therefore, p be the pressure, and g' the force of gravity at the height z; then ϱ being the density, and $d\,z$ the thickness of the slice, we have

$$d\,p = -\,g'\,\varrho\,d\,z \ldots . (2.)$$

Let g be the force of gravity at the foot of the column, or at the surface of the earth, and r the mean radius of the earth = 20,887,030 feet (*see* EARTH); then, neglecting the small variation of centrifugal force due to the height z, $g' = g\,r^2 \div (r + z)^2$. Substituting in equation (2.) this value of g', and eliminating ϱ by means of equation (1.), there results

$$\frac{d\,p}{p} = \frac{-\,g\,r^2\,d\,z}{k\,(1 + \alpha\theta)\,(r + z)^2}.$$

Integrating this equation on the supposition of θ being constant, and determining the constants so that $p = \varpi$ when $z = 0$, we find

$$\log.\frac{\varpi}{p} = \frac{+\,g\,r\,z}{k\,(1 + \alpha\theta)(r + z)} \ldots . (3.)$$

To apply this formula to the determination of the difference of altitudes of two stations, let

h, h' = heights of the mercury in the barometer at the lower and upper stations respectively in inches,
m, m' = the densities of the mercury at the two stations,
T, T′ = the temperatures of the mercury (in centigrade degrees),
t, t' = the temperatures of the air,
g, g' = force of gravity at the lower and upper station,
ϖ, p = the pressures; then

$$\varpi = m\,g\,h,\; p = m'\,g'\,h'.$$

Now it has been determined by experiment that the density of mercury increases by the 1-5550th part for each centigrade degree by which the temperature diminishes; therefore,

$$m' = m\left(1 + \frac{T - T'}{5550}\right);\ \text{and}\ g' = g\,\frac{r^2}{(r + z)^2};$$

whence, assuming $c = 1 + \dfrac{T - T'}{5550}$, $\dfrac{\varpi}{p} = \dfrac{h\,(r + z)^2}{c\,h'\,r^2}$,

and therefore

$$\log.\frac{\varpi}{p} = \log. h - \log. c\,h' + 2\log.\left(1 + \frac{z}{r}\right).$$

Substituting this in equation (3.), and transposing,

$$z = \frac{k}{g}\,(1 + \alpha\theta)\left[\log. h - \log. c\,h' + 2\log.\left(1 + \frac{z}{r}\right)\right]\left(1 + \frac{z}{r}\right) \ldots . (4.)$$

It now remains to convert the quantities in this formula (all of which are known excepting z) into numbers.

1. The logarithms which enter the equation being hyperbolic, in order that the tabular logarithms may be used it is necessary to divide the second member by the modulus M = ·43429.

2. The quantity k, which expresses the ratio of the pressure or elastic force of atmospheric air to its density, depends upon the force of gravity as well as on the temperature, and must therefore be determined with respect to some particular place. Let G denote the accelerating force of gravity at Greenwich, H the standard height of the barometer, m the density of mercury, and D that of air, both at the freezing temperature; then $\varpi = m$ G H, and $k = \dfrac{\varpi}{D} = \dfrac{m\,H}{D}\cdot G$. For the height, H = ·76 metres, or 2·449348 feet, the ratio of m to D, in respect of dry air, was found by Biot and Arago to be 10462. According to this determination, we have k = 26086·8 × G. For air saturated with moisture, they found k = 26152·3 × G. Hence if we adopt the mean of the two coefficients as representing the ordinary state of the atmosphere, we have

$$k = 26120 \times G,\ \text{in feet.}$$

3. The gravity, g, in equation (4.) is that which corresponds to the lower station, and to the latitude of the place of observation. Denoting the latitude of the station by l, and that of Greenwich (to which G corresponds) by L, we have from the theory of the earth

$$\frac{g}{G} = \frac{1 + n\sin. 2\,l}{1 + n\sin. 2\,L} = \frac{1 - \frac{1}{2}n\cos. 2\,l}{1 - \frac{1}{2}n\cos. 2\,L}$$

(very nearly). Here the coefficient n is $\frac{5}{2}$ times the ratio of the centrifugal force to gravity at the equator, diminished by the ellipticity, or $\frac{5}{2} \times \frac{1}{289} \times \frac{1}{302}$ = ·005145 (*see* EARTH); and $\frac{1}{2}n$ = ·00257. But L = 51° 28′ 39″, and cos. 2 L = — ·2242; whence we find

$$g = \frac{(1 - \cdot 00257)\cos. 2\,l}{1\cdot 00058}\,G,$$

and we have therefore in feet

$$\frac{k}{M\,g} = \frac{26120 \times 1\cdot 00058}{\cdot 43429\,(1 - 00257\cos. 2\,l)} = \frac{60168}{1 - \cdot 00257\cos. 2\,l}$$

4. For θ we may take $\frac{1}{2}(t + t')$, the mean temperature of the lower and higher station. In the case of perfectly dry air, α = ·00375; but as the density of air mixed with vapour increases as the temperature is diminished in a faster ratio than dry air, we may assume as the nearest probable value, α = ·004. This gives $\alpha\,\theta = \dfrac{2\,(t + t')}{1000}$.

For the sake of abridging, put

$$K = \frac{60168}{1 - \cdot 00257\cos. 2\,l}\left(1 + \frac{2\,(t + t')}{1000}\right),$$

then the equation (4.) becomes

$$z = K\left[\log. h - \log. c\,h' + 2\log.\left(1 + \frac{z}{r}\right)\right]\left(1 + \frac{z}{r}\right).$$

In computing from this formula, an approximate value of z is obtained by making

$$z = K\,(\log. h - \log. c\,h');$$

by the substitution of which in the second member of the above equation a more exact value is found, and the result is the height of the second station above the first in feet.

Instead of the numerical factor 60168 feet in the coefficient K, Poisson (*Mécanique*, tom. ii.) has 18337·46 mètres, which is equal to 60163 feet. The difference arises from our having assumed a slightly different value for the eccentricity of the earth, and having referred the gravity G to the latitude of Greenwich instead of Paris.

The temperatures have been assumed to be expressed on the centigrade scale, as the most convenient for computation. If T and t are for Fahrenheit's thermometer, it is only necessary to substitute $1 + \dfrac{T - T'}{9990}$ for $1 + \dfrac{T - T'}{5550}$, and $1 + \dfrac{t + t' - 64}{900}$ for $1 + \dfrac{2\,(t + t')}{1000}$, respectively, in the factors c and K.

When the altitude is not very considerable, the fraction $z \div r$ is very small, and may be considered as constant; in which case it may be incorporated with the factor 60168. Substituting for 60168 the number 60345 (deduced from a number of measurements by Ramond), and supposing the substitution to change K into K′, the formula for the altitude will become

$$z = K'\,(\log. h - \log. c\,h'),$$

which is the formula most frequently used.

The most recent and complete investigation of the

subject of barometric measurements is that of Bessel, in *Schumacher's Astronomische Nachrichten*, vol. xv. See also Biot, *Astronomie Physique*, tom. iii.

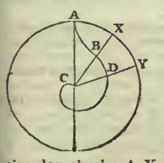
HEIR. (Lat. hæres.) In Law, one who succeeds by descent to lands, tenements, and hereditaments. Strictly speaking, a person is not properly called heir in the lifetime of his ancestor; according to the ancient maxim, *nemo est hæres viventis*. (For the rules which govern this succession in England by common law and statute, see Descent.) *Heir-apparent* is he who (by law or custom) must succeed, by descent, to the hereditaments, if he survive the present tenant; as, at common law, the eldest son. *Heir-presumptive*, he who stands nearest in succession in the default of an heir-apparent; as an eldest brother where there is no issue. *Heir-at-law*, or *heir-general*, is he who succeeds by descent to lands in fee-simple. *Heir-special*, issue in tail claiming by the form of the gift. (*See* Fee-Tail.) *Heir by custom*, he who succeeds to lands or tenements by custom; as all the sons by gavelkind. *Heir-male*, i. e. the nearest male in the succession, is not strictly a term of English law, since lands cannot descend in this way; but some dignities are thus limited. A devisee is sometimes called *heir by devise*, or *hæres factus*. Bastards, aliens, persons attaint of treason and felony, cannot be heirs; but idiots and lunatics may. Things that pass with the land, as conditions and covenants real, goods and chattels annexed to the freehold (*see* Fixtures), and terms of years to attend the inheritance, are in ordinary legal language said to go to the heir: as also *heir-looms*, being such goods and chattels as go by special custom along with the inheritance. In Scottish law, the word *heir* is taken in a larger acceptation, as to personal as well as real property. Heirs-at-law are termed in it *heirs whatsomever*. It recognizes several species of heirs: as the heir-active, who has the right of action; heir of line, or lineal heir; heir by conquest, who succeeds to estates to which the deceased donor did not himself succeed by descent; heirs portioners, in English law coparceners; heir of tailzie (or in tail), and so forth. By the civil law, heirs are of two kinds — legitimate, or by act of law; and instituted, or by the will of the possessor: the former only answering to those who are properly designated as heirs in our own law, the latter to our *purchasers*. Legitimate are either *heirs of blood* — heirs under the title "unde vir et uxor" (by which, in default of heirs of blood, a husband or wife succeeded to the goods of the deceased spouse; a provision not generally preserved in modern Continental law); and heirs *irregular*, — such as the lord to whom an escheat falls, &c. Heirs instituted are of many kinds.

HEIR-LOOMS. In Law, such goods and personal chattels as go to the heir along with the realty. The quality of heir-looms is fixed by custom; deeds, charters, deer in a park, &c., are usually such. "Loom" is from an old Saxon word "limb," or member.

HELI'ACAL. (Gr. ἥλιος, *the sun*.) Something relating to the sun. In the ancient astronomy, a star is said to rise *heliacally* when, after being in conjunction with the sun, and consequently invisible, it rises so soon before the sun as to be visible in the eastern horizon in the morning twilight; and it is said to set *heliacally* when the sun approaches so near to it that it is lost in his light, or ceases to be visible in the western horizon when he has disappeared. At the opposite season of the year the same star rises as the sun sets, and sets as the sun rises; it is then said to rise and set *acronically*. When a star or planet rises and sets at the same instant with the sun, it is said to rise and set *cosmically*. These technical terms occur frequently in the works of Hesiod, and in Ovid's *Fasti*. The ancients fixed the commencement of the seasons by the positions of the stars relatively to the sun at his rising and setting.

HELIÆ'A. (Gr. Ἡλιαία.) In Ancient History, the chief of the ten courts among which the 6000 Athenian jurymen were distributed, and which on important occasions sometimes contained them all. It probably derived its name from being open to the sun (ἥλιος). Before this tribunal causes of consequence to the state and individuals which did not involve bloodshed were brought. (See *Mem. de l'Acad. des Inscrip.* vol. xviii.; *Boeckh's Public Economy of Athens*.)

HE'LICOID, or PARABOLIC SPIRAL (Gr. ἕλιξ, *a spiral*), in Geometry, is a curve line which is generated as follows: — Suppose the axis of the common or Apollonian parabola to be bent into the circumference of a circle, the ordinates X B, Y D, still retaining their places and perpendicular positions with respect to the axis; then the spiral curve, A B D, which passes through the extremities of the ordinates, is the helicoid. It is obvious from this definition that all the ordinates, being perpendicular to the circumference of the circle, meet in its centre C; and if x represent any circular absciss A X, and y the corresponding ordinate

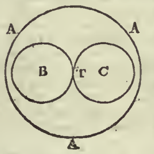


X B, the equation of the curve will be the same as that of the parabola; namely, $y^2 = a\,x$, a being the parameter.

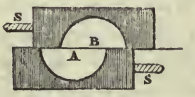
HE'LIOCAMI'NUS. (Gr. ἥλιος, *the sun*, and καμινος, *a furnace*.) In Ancient Architecture, an arched apartment heated by the rays of the sun.

HE'LIOCE'NTRIC. (Gr. ἥλιος, and κεντρον, *centre*.) The *heliocentric longitude* of a planet is the angle at the sun's centre, formed by the projection of its radius vector on the ecliptic and the straight line drawn from the centre of the sun to the first point of Aries; and the *heliocentric latitude* of a planet is the inclination of the straight line which joins its centre with that of the sun to the plane of the ecliptic. The greatest heliocentric latitude is consequently equal to the inclination of the planet's orbit.

HELIO'METER. (Gr. ἥλιος, and μετρον, *measure*.) A kind of micrometer for measuring the diameters of the sun, moon, and planets, or any small apparent distance between celestial objects. The instrument best known by this name appears to have been proposed or suggested by a Mr. Savery (*Phil. Trans.* vol. xlviii.), about the year 1743; but it was first applied by Bouguer in 1747, and has since been improved by Dollond and Fraunhofer. The principle on which the instrument is constructed is as follows: — Two object-glasses of the same focal distance, or rather the two halves of a divided object-glass, are placed side by side in the same tube with an apparatus so contrived that the distance between the centres can be increased or diminished at pleasure. In this manner two images of the sun are formed at the focus of the common eye-glass. Thus the circle A A A representing the field of view of the telescope, or the visible circle at the common focus of the two object-glasses and the eye-glass, and the two small circles representing the two images of the sun formed by the two object-glasses, when the observer proposes to measure the diameter of the sun, the two object-glasses are brought by means of a tangent screw to such a distance from each other that the two images touch in a point T, and the distance between the centres of the two object-glasses, estimated in seconds, gives the distance between B and C, the centres of the images; that is, the diameter of the sun.

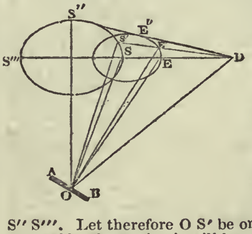


Formerly the heliometer was formed by two complete lenses; but as it was found very difficult to give them precisely the same focal length, and as the size of the tube was required to be inconveniently large, they are now made of the same lens by dividing it across its centre. The centres of the two semi-lenses are separated by means of the screws S S, which act on the plates in which they are mounted; and the distance of the centres A and B is measured by a scale and vernier. This apparatus is otherwise called the *divided object-glass* micrometer. The principle has also been applied to the microscope. *See* Micrometer.



HE'LIOSCOPE. (Gr. ἥλιος, and σκοπεω, *I view*.) The name given by Scheiner to an instrument of his own invention for observing the sun without hurting the eye. The ordinary method is to place a disc of coloured glass before the eye-piece of the telescope.

HE'LIOSTAT. (Gr. ἥλιος, *the sun*, and στάω, *I stand*.) An instrument invented by Gravesande for the purpose of obviating in optical experiments the inconvenience arising from the continual change of direction of the solar rays, by reflecting them in the same straight line. The principle on which the heliostat is constructed may be explained as follows: — Let S S′ S″ S‴ be the diurnal circle described by the sun, O a point on the surface of the earth which may be regarded as the centre of the circle S S′ S″ S‴, A B the mirror, and O D the direction in which it is required that the ray shall be reflected. The solar rays will successively coincide with the straight lines which form the sides of the conical surface O S S′ S″ S‴. Let therefore O S′ be one of these rays, and let us consider the motion it will be necessary to give to the mirror in order that all the rays O S, O S′, &c. may be reflected by the mirror in the direction OD. Produce OD till it meet the plane of the earth's diurnal circle in D, and let D S S‴ pass through the centre of the circle. Join D S′, and draw O E′ at right angles to A B, meeting D S′



in E′. The angles of incidence and reflexion being equal, the angle S′ O E′ is equal to E′ O D: therefore S′ E′ is to E′ D in the ratio of S′ O to O D. But S′ O and O D are constant, therefore the ratio of S′ E′ to E′ D is constant. But D is a given point; therefore by a simple theorem in elementary geometry (*Leslie's Geom. Analysis*, b. iii. prop. 2.) the locus of E′ is a given circle. It follows, therefore, that the axis of the mirror must describe in 24 hours the surface of a cone, the base of which, parallel to the plane of the equator, is a circle determined in magnitude and position by the given direction O D, and the parallel which the sun is describing on a given day of the year.

It is easy to conceive a mechanism by which this object may be accomplished. Suppose a clock to be placed with its dial parallel to the equator, or the axis of the index hands parallel to the axis of the earth; and suppose a rod connected with the extremity of the hour hand to meet the axis produced and make with it the proper angle; then a mirror fixed perpendicularly to the rod will have the motion required.

For a description of the original instrument see *Gravesandes' Phys. Elementa;* but it has been greatly improved by Charles, Malus, &c. See *Journal de l'Ecole Polytechnique*, cahier 16.; *Biot, Physique Experimentale*, tom. ii.

HE′LIOTROPE. A deep-green siliceous mineral, somewhat translucent, and often variegated with blood-red spots: from Gr. ἡλιος, *the sun*, and τϱεπω, *I turn*. Its vulgar name is *bloodstone*. There is also a common sweet-scented *plant* of this name.

HE′LIX. (Gr. ἑλιξ, *a whorl.*) The name of a Linnæan genus of the *Vermes Testacea*, characterized by the entire and crescent-shaped opening of the shell, and forming in the system of Cuvier the type of a family of terrestrial and air-breathing Gastropods, including the genera *Vitrina*, Draparnaud; *Bulinus*, Adanson; *Pupa*, Lam.; *Chondrus*, Cuv.; *Succinea*, Drap.; and *Helix* proper, of which our common garden snail, *Helix hortensis*, is an example.

The great vine snail (*Helix pomatia*, Linn.) formed one of the luxuries of the tables of the ancient Romans, and by peculiar feeding and other treatment was brought to attain an immense size. It is still an article of food in certain cantons in Switzerland and France. The snails do much damage to the vegetables in cultivated grounds, biting off pieces of the leaves by means of a semicircular dentated horny plate, which is affixed to the upper lip.

Helix, in Anatomy, is applied to the reflected margin of the external ear.

Helix, Helices. In Architecture, the curling stalks or volutes under the flowers in each face of the abacus of the Corinthian capital.

HE′LLEBORE. (Gr.) In Pharmacy, this term is applied to the roots of the black and white hellebore. The root of black hellebore (*Helleborus niger*), called also *Melampodium*, has a bitterish acrid taste, and is a drastic purge and emetic: the root of the white hellebore is similar, but more active in its operation. (*See* Veratria.) It was formerly used in the cure of gout, and in some maniacal cases where no effect is produced except by very powerful means; but these remedies have now fallen into disuse. The leaves of the *Helleborus fœtidus*, or stinking hellebore, have also been used to evacuate worms from the intestines; but they are dangerously active.

HELLE′NIC. The name given to the common dialect which prevailed very generally among the Greek writers after the time of Alexander. It was formed, with very slight variations, from the pure Attic of the age preceding its introduction.

HELLENI′STIC. The name given to that dialect of the Grecian language that was used by the Jewish writers. Its peculiarities consisted in the introduction of foreign words very little disguised, but more especially of oriental metaphors and idioms; but not at all in the inflexions of words, which were the same as in the Hellenic.

HE′LLENISTS (Gr. ἑλληνισται, from Ἑλλην, *a Greek*), the name by which the Jews who from their foreign birth or travel used the Greek (Hellenic) language are distinguished in the Acts of Apostles. The word is derived, according to a common method of formation in the Greek language, from the verb ἑλληνιζειν, *to Hellenize*, or adopt the manners of a Greek. There were great numbers of Jews scattered throughout the Roman empire at this period, more especially in the Asiatic and East African provinces, where the Greek was the current language; and as they were in the habit of making frequent journeys to and from Jerusalem, they heard the preaching of the Apostles, and became efficacious instruments in conveying the knowledge of the word throughout all lands. From their long sojourn in foreign countries they were distinguished from the Hebraists, or native Jews, by the greater liberality of their views with respect to the nature of the promises of the Old Testament. It appears from Acts, vi. 1., that these Jews retained the distinctive name of Hellenists after their conversion to Christianity, and that there continued to subsist some jealousy between them and the native Christians.

HELM, implies the mechanism of the steerage, especially the tiller: as, to put the helm *a-starboard*, is to put the tiller over to the right side; *a-port*, to the left side; *up*, to the weather side; *down*, to the lee side.

HELM, or HE′LMET. Defensive armour for the head: a word of Scandinavian derivation. The armour of the ancients, which particularly guarded the head, was known by the general denominations of head-piece, casque, and helmet. Helmets were anciently formed of various materials, but chiefly of skins of beasts, brass, and iron. An open helmet covers only the head, ears, and neck, leaving the face unguarded. Some open helmets have a bar or bars from the forehead to the chin, to guard against the transverse cut of a broad-sword; but it affords little defence against the point of a lance or sword. A close helmet entirely covers the head, face, and neck; having on the front perforations for the admission of air, and slits through which the wearer may see the objects around him; this part, which is styled the visor (from the French word *viser*, to take aim), lifts up by means of a pivot over each ear. Some helmets have a bever (from *buveur*, drinker, or from the Italian *bevere*, to drink), which, when closed, covers the mouth and chin, and either lifts up by revolving on the same pivots as the visor, or lets down by means of two or more pivots on each side near the jaws. The use of the bever was to enable the wearer to eat and drink more commodiously than could be done in a helmet with a visor only. The helmets of the Greeks and Romans were mostly open, not unlike scull-caps, as formerly worn by our dragoons. Montfaucon says he never saw an ancient helmet with a visor to raise or let down, although he is of opinion that they had those contrivances. It seems as if the Romans, at least those of which Pompey's army was composed at Pharsalia, had open helmets, as Cæsar directed his soldiers to strike them in the face, which order, had their faces been covered, he would not have given. The two Grecian helmets in the British Museum have a kind of contrivance to cover the nose. Over the top of the helmet rose an elevated ridge called the crest, representing lions or dragons, &c., to make the warrior appear taller and more terrible. (*Mirror*, 1839.)

HELMET, or HELMET-SHELLS. *See* Cassis.

HELMINTHO′LOGY. (Gr. ἑλμινς, *a worm*, and λογος *a discourse*.) The natural history of worms. *See* Intestinalia.

HE′LMSMAN. The man who steers. A good helmsman opposes in time the tendency of the ship to deviate from her course by a small motion, which he relaxes as soon as the effect is felt, and thus disturbs her sailing as little as possible. A bad helmsman gives her too much helm, and keeps her perpetually yawing from one side to the other. The steerage, therefore, is of the utmost consequence in chase.

HELO′PIDÆ. (Gr. Ἑλοψ, the name of an obnoxious reptile.) A family of Heteromerous Coleopterans, belonging to the section *Stenelytra*, and including numerous subgenera and species. The typical genus *Helops* is remarkable for having the anterior tarsi of the males dilated. Of this genus there are four British species known, of which the *Helops caraboides* may be found at the roots and under the bark of trees: it presents a lengthened ovate form, a brown colour, a punctured surface, and dusky red antennæ and tarsi.

HE′LOTS. (Gr. εἱλῶται.) In Ancient History, the slaves of the Spartans, who consisted originally of the Achæan inhabitants of Laconia, who were subdued by force of arms by the Dorian invaders. The name was derived from Helos, a town of Laconia, of which the inhabitants were thus reduced to servitude; but to this class were afterwards added the Messenians, who still clung to their native soil after its subjugation by the Spartans. They were employed either as domestic slaves, cultivators of the land, or in the public works; and though they do not appear to have been treated ordinarily with much severity, yet the recollection of their former state urged them frequently to revolt, while their numbers rendered them so formidable to their masters as to drive the latter to schemes of the most abominable treachery for their repression. (See particularly *Müller's Hist. of the Dorians;* Wachsmuth, *Hist. Ant. of the Greeks* (transl.) i. 323.)

HE′LVER. A miner's term; the handle of a tool.

HE′MACRYMES, *Hemacryma*. (Gr. αἷμα, *blood*, and κϱυμος, *cold*.) A name by which Latreille designates the animals with cold blood.

HE′MATHERMS, *Hematherma*. (Gr. αἷμα, θεϱμη, *heat*.) The name given by Latreille to the animals with warm blood.

HE′MATIN. (Gr. αιμα.) The red colouring principle of logwood.

HE′MATITE. One of the varieties of native oxide of iron. It occurs in nodules, and in radiated masses of a crystalline fracture. Its name is derived from the red colour which it presents superficially or when rubbed to powder.

HEMATOSIN. *See* HÆMATOSINE.

HEME'LYTRA. (Gr. ἡμισυς, *half;* ἐλυτρον, *a sheath.*) The name given to the superior wings or wing-covers of Tetrapterous insects, when they are coriaceous at the base and membranous at the extremity; as in the order *Hemiptera.*

HE'MERALOPIA. (Gr. ἡμερα, *day,* and ωψ, *the eye.*) A disease of the eye which renders vision very imperfect except in broad daylight; it has been relieved by tonics and gentle stimulants, with the occasional application of blisters behind the ears.

HE'MEROBAPTISTS. (Gr. ἡμερα, *day;* βαπτιζω, *I baptize.*) An ancient sect among the Jews, so called from washing themselves as a religious solemnity every day. It is thought by some that the Christians of Saint John, or Sabians, descend from them. (*Mosheim,* Transl., ed. 1826, iv. 226.)

HEMERO'BIANS, *Hemerobiidæ.* (Gr. ἡμερα, and βιος, *life.*) A family of Neuropterous insects, of the section called *Planipennes* by Latreille; characterized by having a slender body, which is greatly exceeded in length by the finely reticulated wings. The ova are deposited in clusters, attached each by a long glutinous pedicle to the leaves of various plants; and by some mycologists have been described as fungi. The larvæ of these insects are remarkable for their ravenous habits; and as they feed chiefly on the plant-lice (*Aphides*), are highly beneficial. They subsist on their juices, suck them to death, and with a singular instinct they clothe themselves with the skins of their victims. Of the typical genus *Hemerobius* there are fourteen known British species, of which the *Hem. perla,* Linn., is the most beautiful. It is sometimes called the "golden-eye;" is of a green colour; the wings transparent, and veined with green.

HEMICRA'NIA. (Gr. ἡμισυς, *half,* and κρανιον, *the head.*) A pain of one side of the head: it is often intermittent.

HEMI'GAMOUS. (Gr. ἡμισυς, and γαμος, *marriage.*) In Botany, a term employed in speaking of grasses, when of two florets in the same spikelet one is neuter and the other unisexual, whether male or female, as in *Ischæmum.*

HE'MIOLO'GAMOUS. (Gr. ἡμισυς, ὁλος, *entire,* and γαμος, *marriage.*) A term employed in speaking of grasses, when in the same spikelet one of two florets is neuter and the other hermaphrodite, as in several species of *Panicum.*

HEMIO'PIA, or HEMIO'PSIA. (Gr. ἡμισυς, and ωψ, *the eye.*) A disordered vision, in which objects appear divided.

HEMI'PTERA. (Gr. ἡμισυς, and πτερον, *a wing.*) An order of Haustellate insects, having the wing-covers of a consistence intermediate between the elytra of beetles and the ordinary membranous wings. By Latreille the term is restricted to those insects the wing-covers of which are coriaceous at the base and membranous at the top; the term *Homoptera* being applied to those Fabrician *Hemiptera* of which the elytra are deflected and of uniform consistence throughout.

When the *Hemiptera* quit the egg they present the form of small hexapod larvæ, differing but little from the perfect insect save in the absence of wings: before these are acquired the skin is shed several times, during which the larva acquires an increase of general bulk. The pupa is active, and is distinguished by having the wings and elytra concealed in small dorsal cases: the next moulting exhibits the perfect insect with the hemelytra and wings fully developed. The bed-bug (*Cimex lectularius*), and water-boatman (*Notonecta*), are examples of the present order of insects.

HE'MISPHERE. (Gr. ἡμισυς, and σφαιρα, *a sphere.*) In Geometry, the half of a sphere, bisected by a plane passing through its centre. In Astronomy, it is used to designate the half of the terrestrial sphere divided by the equator. Hemisphere also denotes a map or projection of half the terrestrial or celestial sphere on a plane.

HE'MISTICH. (Gr. ἡμιστιχιον; from ἡμι, *half,* and στιχος, *verse.*) In Poetry, half a verse. The unfinished verses in Virgil's *Æneid,* concerning which it is not known whether they were purposely left in that state, or are owing to the incompleteness of the poem, are usually called hemistichs. The alexandrine, or French hemi-verse, requires a regular pause at the end of the first hemistich.

HE'MLOCK. A common umbelliferous plant of a peculiar odour, and possessed of narcotic powers. For medical use the leaves should be collected just before the plant flowers; if intended for powder, they should be carefully dried at a temperature not exceeding 212°; if for extract, the juice should be squeezed out by moderate pressure, and evaporated in a water or steam bath to a proper consistency. The *extract of hemlock* is perhaps the best preparation; but as its activity is liable to vary, it should be given with caution. An average dose is five grains; an over dose produces giddiness, wandering of the mind, dilated pupil, convulsive motions of the muscles of the face, and the other symptoms of this class of poisons. Hemlock is a powerful sedative, and often serviceable as a substitute for or accompaniment to opium. In allaying morbid irritability of the system attended by any local or general excess of vascular action, as in certain stages of phthysis, in the coughs that are apt to hang about patients who have suffered from pulmonic inflammation, in glandular tumours and unhealthy sores, hemlock is often preferable to opium. It has also been found very useful in chronic rheumatism, and occasionally in the treatment of whooping cough. A poultice composed of a mixture of finely powdered fresh hemlock with bread and water, or of the extract of hemlock, is applied to allay the pain of irritable ulcers and cancerous sores: it is sometimes singularly effectual, at others it seems inert, and sometimes appears to increase irritation. The virtues of hemlock reside in a peculiar alkaline principle, which has been termed *conia,* combined in the herb with a distinct acid, the *coneic acid.*

HEMP. (Germ. hanf.) The fibres of the bark of the *Cannabis sativa.* It is prepared for spinning in the same way as flax, and is made into strands or yarn for ropes, sailcloth, &c. This plant is supposed to be a native of India, but it has long been naturalized and extensively cultivated in Italy, and many other countries of Europe, particularly Russia and Poland, where it forms an article of primary commercial importance. It is also cultivated to a considerable extent in many parts of America; but in the United Kingdom it is but little grown, except in a few districts of Suffolk and Lancashire.

HE'NBANE. This is a common plant, flowering in July; the *Hyoscyamus niger.* The expressed juice of the leaves evaporated to the consistency of extract has long been used as a sedative or narcotic. It has a peculiar strong and disagreeable odour, and a nauseous bitterish taste. From two to five grains of the extract of henbane are often found equivalent to about one grain of *opium,* and where the latter disagrees it often produces quiet: in many cases henbane and various forms of opium may be combined. Henbane is apt to produce giddiness; but it does not constipate the bowels, and has rather a diuretic tendency.

HE'NDECASYLLA'BIC. (Gr. ἑνδεκα.) A verse of eleven syllables. The Latin hendecasyllabic, of which the principal specimens left to us are from the pen of Catullus, consist of a spondee, dactyl, and three trochees —

Vivamus, mea Lesbia, atque amemus.

The Italian heroic verse, and those of England and Germany, when increased by the addition of a final short syllable, are iambic hendecasyllabics.

The licence of adding an eleventh syllable (and sometimes also a twelfth) is more frequently admissible in English dramatic than epic versification.

HENRI'CIANS. The followers of an Italian monk of the name of Henry, who in the twelfth century preached with fanatic zeal, principally against the corruptions and impostures of the Romish church. He traversed the south of France from Lausanne to Toulouse, and met with great success at all the towns at which he halted. He rejected the baptism of infants, declaimed vehemently against the vices of the clergy, and exposed the vanity and absurdity of many of the ceremonies of the church. At length his followers were turned against him by the eloquence of St. Bernard, and he died in prison, into which he had been thrown by Eugenius III., in the year 1148. (*Waddington's History of the Church,* c. 10.)

HE'PAR. (Gr. ἡπαρ.) This term, signifying *liver,* was applied by the old chemists to various compounds of sulphur with the metals, having a brown-red or liver colour.

HEPATA'LGIA. (Gr. ἡπαρ, *the liver,* and αλγος, *pain.*) A painful affection of the liver.

HEPA'TICÆ. (Hepar, *liver,* in allusion to the form of some of the species.) A natural order of flowerless plants, growing in damp shady places in all temperate climates; in some respects allied to mosses, and in others to lichens. They are of no known importance; but are interesting to systematic botanists, because they offer strong traces of sexual apparatus in plants of a very low kind of organization.

HEPATI'TIS. (Gr. ἡπαρ.) Inflammation of the liver. The acute or active form of this disease is ushered in with pain in the region of the liver, sickness, costiveness, and a strong, hard, and frequent pulse; there is also generally great pain about the clavicle and shoulder. Bleeding, and purging with salts, senna, and calomel, and a blister, are usually effectual in Europe in subduing an attack of this disease: in warm climates, calomel and mercurials must often be continued till they affect the mouth. In *chronic* hepatitis the same general plan of treatment must be followed up, especially as regards the use of mercurials: with these, and gentle aperients and mild bitters, the yellowness of the complexion, lowness of spirits, and other concomitants of what in warm climates is called *the liver,* are usually subdued, at least in Europe. The chronic hepatitis of India always requires for its permanent cure a change of climate.

HE'PTAGON. (Gr. ἑπτα, *seven*, and γωνια, *angle*.) In Geometry, a plane figure of seven sides. The area of a regular heptagon is equal to the square of one of its sides multiplied into the constant number 3·6339124, or seven fourths of the tangent of the angle at the base to radius 1.

HEPTA'GONAL NU'MBERS, are a kind of polygonal numbers, of which the difference of the terms of the corresponding arithmetical progression is 5. Thus,

Arithmeticals . . . . 1, 6, 11, 16, 21, &c.;
Heptagonals . . . . 1, 7, 18, 34, 55, &c.;

the latter being formed by the continual addition of the terms of the first. Among other properties of heptagonal numbers there is one very remarkable; namely, that if any heptagonal number is multiplied by 40, and 9 added to the product, the sum is a square number.

HEPTANDROUS. (Gr. ἑπτα, and ανηρ, *a man*.) Any flower having seven stamens.

HE'PTARCHY. (Gr. ἑπτα, and ἀρχω, *I govern*.) In English History, the division of England into seven Saxon kingdoms, which are represented in most of our histories to have existed at the same time with and independently of each other. The seven kingdoms in question, according to the common divisions, were Kent, Sussex, Wessex, Essex, East Anglia, Mercia, Northumberland. But in point of fact there was no period of history when these seven kingdoms existed together; and, in the constant fluctuations of conquest, fresh subdivisions and unions of territory were continually made by the fortune of war. The sovereign who succeeded in obtaining a temporary supremacy over his neighbour kings generally assumed the title of Bretwalda, or ruler of the Britons, of whom Ella, king of Wessex, was the first; but it was afterwards borne by kings both of Kent, East Anglia, and Northumbria. In 617, Edwin, king of the atter district, appears to have acquired a temporary sovereignty over the whole of England, which was also gained by his nephew Oswald in 634; but after the brother of the latter king, Oswio, no Saxon monarch assumed the title of Bretwalda. After the death of the latter Mercia rose in the scale; and its king, Offa, ruled nearly the whole of the Saxon territories in the last half of the eighth century. After his death Egbert, king of the West Saxons, raised his power on the ruins of that of Mercia; and having subdued and rendered tributary the other kingdoms then subsisting, he became, about 830, master of the whole Saxon realm, and is reckoned as the eighth Bretwalda or ruler of Britain. With his reign the heptarchy is usually considered to have ended. (See *Palgrave's History of England*; *Turner's Anglo-Saxons*.)

HERA'CLEONITES. An early sect of heretics belonging to the Gnostics, so called from Heracleon, whose tenets they embraced. They rejected all the ancient prophecies, regarded themselves as superior to the Apostles, and, under the pretext of a sublime or elevated exposition of the Scriptures, propounded the wildest and most extravagant paradoxes.

HERACLI'DÆ. A general designation for the descendants of Hercules, who, after the death of that hero, were expelled from the Peloponnesus by Eurystheus, king of Mycenæ. The return of the Heraclidæ, which took place about 140 years after their expulsion, or 80 years after the siege of Troy, forms a celebrated epoch in ancient chronology, as it has been generally considered to mark the transition from the heroic or fabulous ages to the period of authentic history.

HERÆ'A. The name of a celebrated festival instituted at Argos in honour of Juno, whom the Greeks called Hera. Another festival of this name, in honour of the same goddess, was held at Elis every five years.

HE'RALD. (Gr. κηρυξ.) An officer of arms, possessed of important functions. The ancient heralds (κήρυκες among the Greeks, feciales among the Romans) were privileged persons, sacred by superstition as well as by the law of nations. Modern heralds, besides their employment on messages between states and in matters of public negotiation (in which capacity their services are grown into disuse, or become merely subordinate), acquired a new character from the prevalence of hereditary devices on coats of arms early in the middle ages. The multiplicity of these inventions rendered it necessary that there should be certain persons about a court skilled in interpreting or in "blazoning" them; according to the rules of the imaginary science to which these fanciful creations were subjected. (*See* HERALDRY.) It became also necessary that they should have a perfect knowledge of the hereditary arms, ensigns armorial, badges of honour, &c. belonging to each family, in order that they might constitute an authority to which appeal might be had in the disputes which frequently arose respecting the rights of individuals to these honourable distinctions. Hence the heralds became, in modern European countries, the depositaries of much of the genealogical science which is conversant in the pedigrees of noble or gentle families. They have also important parts to fulfil on occasions of public solemnity, pageants, installations, nuptials, funerals, &c. Edward III. was the first English sovereign who created two heraldic kings-at-arms (Surroy and Norroy), whose office was exercised south and north of Trent respectively. Richard II. gave the earl-marshal power to preside in a court of chivalry, assisted by the heralds. But the first heraldic collegiate chapter was held at the siege of Rouen, in 1420. The kings-at-arms were fixed at three, their present number, by Henry VIII. Edward VI. fixed the establishment of heralds on the site of the building which they at present occupy in the city of London. The present Heralds' College (by which name the kings-at-arms, heralds, and pursuivants are incorporated) consists of— 1. Three kings-at-arms — Garter, Clarencieux, and Norroy; of whom the first holds the highest rank. His duties are chiefly to grant supporters, arrange funerals, and present the order of the Garter to foreign princes. 2. The heralds are six in number; styled Windsor, Chester, Lancaster, Somerset, York, and Richmond: they, with the kings-at-arms, form the collegiate chapter. 3. The four pursuivants (Portcullis, Rouge Dragon, Blue Mantle, and Porte Croix) are junior officers, or probationers, who afterwards succeed to the higher offices. The duties of the officers of the Heralds' College are various, and their powers have been considerable, although curtailed by modern indifference to the purity of their ancient science. They keep the records of the arms, crests, and cognizances of every gentleman, *i.e.* person entitled to bear them; and they have considerable authority for the purpose of preventing parties from bearing arms to which they have no right. Their title to confer arms, or rather to assign coats of arms to persons applying for permission to bear them, is still generally recognized. Heraldic visitations of counties, with a view to collect information on the subject of genealogies and coat-armour, was held as early as the reign of Henry IV. In 1528, a regular commission was granted for the whole kingdom; and visitations were held at intervals of twenty or thirty years from that time to the beginning of the last century. (See *Noble's History of the College of Arms*, 1805.)

HE'RALDRY. The science of conventional distinctions impressed on shields, banners, and other military accoutrements. Heraldry has been divided into personal and national. The first of these treats of bearings belonging to individuals, either in their own or in hereditary right. Devices adopted by champions in the field, and borne on their shields or on their banners, are of very high anquity. The sculptures on the shields of Achilles and Hercules, in *Homer* and *Hesiod*, are rather ornamental than heraldic. But in the Seven Chiefs against Thebes of Æschylus, we find the cognizances of these renowned leaders distinctly blazoned, as worn by them on their shields, in the same fashion with those of the knights in the middle ages. The Romans do not seem to have had any customary devices for individuals resembling our armorial insignia; except their distinctive crowns for particular services. The jus imaginum, or right of possessing small

---

EXPLANATION OF THE PLATE.

I. *Lines.*

1. Horizontal or straight. 2. Angled. 3. Bevilled. 4. Escartelé 5. Nowy, or Franché. 6. Arched, or enarched. 7. Double arched. 8. Wavy, or undée. 9. Invected. 10. Engrailed. 11. Battled-embattled, or crenellée. 12. Battled-embattled. 13. Nebuly. 14 Potent. 15. Indented. 16. Dancettée. 17. Dove-tailed. 18. Urdée. 19. Rayonnée, or radiant.

II. *Points of the Escutcheon, Colours, and Furs.*

20. Escutcheon, points of. 21. Or. 22. Argent. 23. Gules. 24. Azure. 25. Sable. 26. Vert. 27. Purpure. 28. Tenne. 29. Sanguine. 30. Ermine. 31. Ermines. 32. Erminois. 33. Pean. 34. Vair. 35. Varry cuppy.

III. *Differences, or Filiations.*

36. (First son) Label of three points. 37. (Second) Crescent. 38. (Third) Mullet. 39. (Fourth) Martlet. 40. (Fifth) Annulet. 41. (Sixth) Fleur-de-lys.

IV. *Ordinaries, &c.*

42. Chief. 43. Pale (between two annulets). 44. Pallet. 45. Party per pale. 46. Border. 47. Bars. 48. Fess. 49. Bend. 50. Bend sinister. 51. Border. 52. Chevron. 53. Cross. 54. Cross of St. John of Jerusalem, or Malta. 55. Cross patonce. 56. Cross moline. 57. Cross of St. Andrew. 58. Crosses humettée. 59. Cross moline in saltier. 60. Cross bottonée, or trefoil. 61. Cross crosslet, fitchée. 62. Cross flory. 63. Cross mascle. 64. Cross fitchée. 65. Lozenge, fleury.

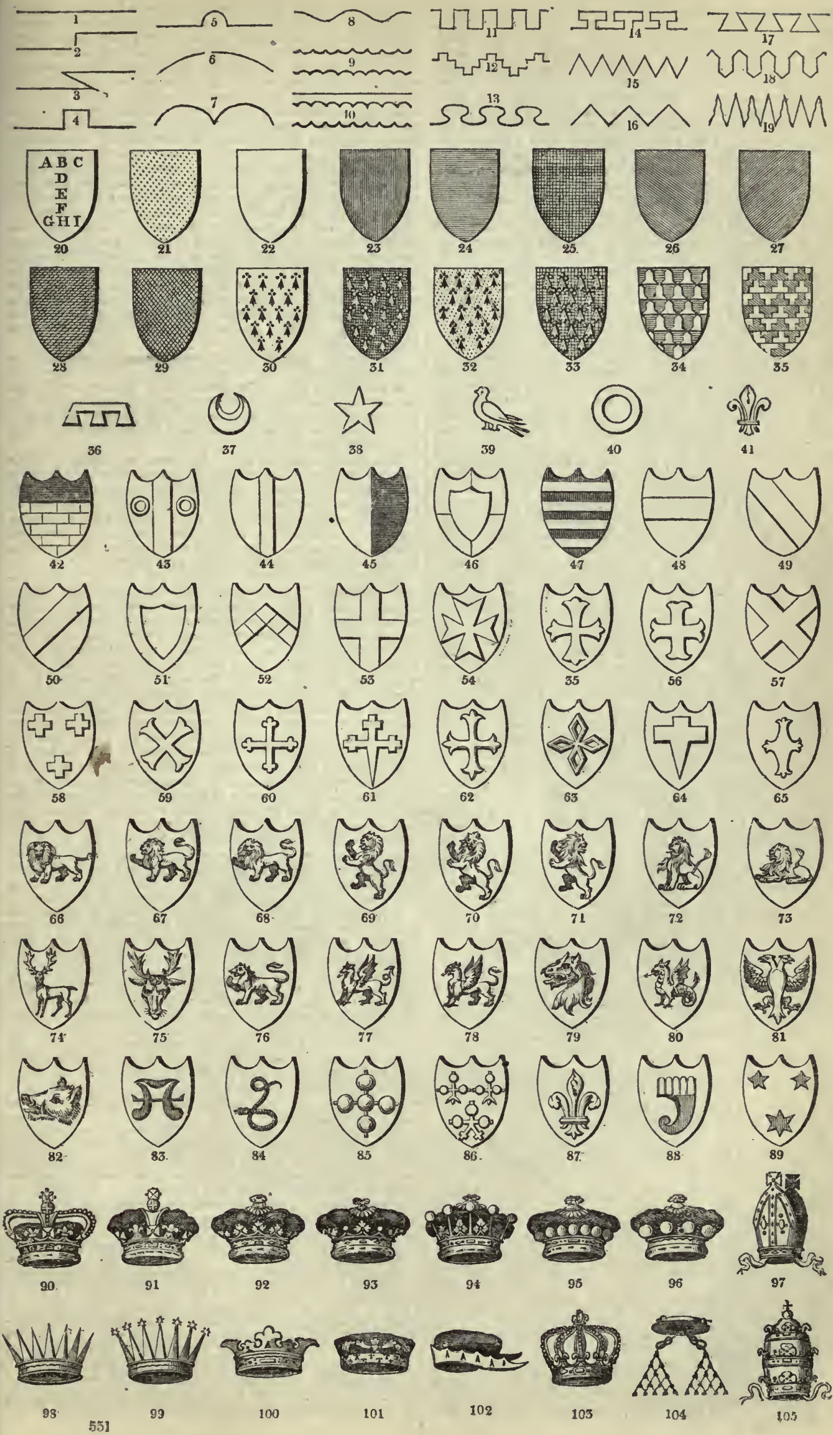
V. *Miscellaneons Bearings.*

66. Lion, statant guardant. 67. Passant. 68. Passant guardant. 69. Rampant. 70. Rampant guardant. 71. Rampant reguardant. 72. Sejant. 73. Couchant. 74. Stag at gaze. 75. Stag's head caboshed. 76. Tiger, heraldic. 77. Dragon. 78. Griffin. 79. Dragon's head erased. 80. Wivern. 81. Eagle displayed, with two heads. 82. Boar's head erased. 83. Water-budgets. 84. Snake, bowed-debruised. 85. Quatrefoil. 86. Trefoils. 87. Fleur-de-lys. 88. Clarion, or rest. 89. Mullets.

VI. *Crowns, Coronets, &c.*

90. Crown of England. 91. Coronet of the Prince of Wales. 92. Coronet of a duke. 93. Marquis. 94. Earl. 95. Viscount. 96. Baron. 97. Mitre of a bishop. 98. Eastern, or antique coronet. 99. Celestial crown. 100. Crown of Edward I. 101. Mortier, or cap of state. 102. Chapeau, or cap of maintenance. 103. Crown of France. 104. Cardinal's hat. 105. Crown triple, or tiara of the pope.

The principal of these heraldic terms will be found explained under their several articles in the Dictionary.



1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19

statues of distinguished individuals of the family, seems to have been their only external hereditary distinction. Early in the middle ages, however, we find abundant notice of cognizances borne by individuals. These were more especially in use in tournaments, where the knights, being clad in complete armour, were unknown to the spectators, except by their banner or shield (*see* BLAZONRY); and probably it was in the lists of the tournament that the fanciful science of heraldry first found its subject matter. This science appears to be a compound of inventions collected from very different quarters. The East, the land of allegory and symbol, seems to have contributed many of its most singular devices. Its ordinaries, colours, metals, and gens, are said to be derived from Germany; and German heraldry appears to be a national science, from the circumstance that its terms of art are nearly all of native origin. But the Normans and French undoubtedly cultivated it with the greatest success, and reduced it to its present systematic form. Our English terms of heraldry are, as is well known, derived entirely from the French language, although not wholly from France; as some additions were made to the science by the Norman-English. Hereditary coat-armour, it is said, cannot be traced with certainty to an earlier period than the 13th century; but it seems that, in the reign of Henry III., the vocabulary of heraldry was nearly as full and definite as at the present day. National heraldry, or the adoption of distinctive emblems by civil communities, is far more ancient than personal. Badges, we know, were borne on the national standards of antiquity: an eagle was the device of Persia and of Rome, an owl of Athens, &c.; and Turkey and Persia, where personal heraldry is unknown, possess at this day national ensigns of correct heraldic character.

Arms are said, in the heraldic science, to be of dominion or pretension (national); arms of community, belonging to episcopal sees, cities, corporations; arms of patronage, to governors of provinces, &c.; arms of concession, or augmentations of honour, granted by sovereigns to individuals, which in the next generation become hereditary; arms of family, or hereditary arms; arms of alliance, showing the union of families and relations of individuals (marked by various devices termed differences, &c.; *see* DIFFERENCE); arms of succession, which accompany the possession of certain estates or lordships; and, finally, arms of assumption, taken up by individuals from caprice or vanity, which, although common enough in the present day, are borne in violation of all heraldic laws; or, arms taken up with the permission of the sovereign, through his principal herald (in England, king at-arms). Armorial bearings were chiefly displayed, in the times of chivalry, on the shield or escutcheon. They were also borne on the pennon, or banner; on sword-hilts, as early as A.D. 1250; on the mantle or surcoat (hence the phrase coat-of-arms); and, in modern times, on carriages or articles of furniture. The science of heraldry, united as it is with that of family genealogy, was for centuries one of the most favourite literary pursuits (if it can be termed such) among the higher ranks of the community. It has been enriched with much legendary knowledge, and diversified with many fanciful antiquarian theories. It is entitled to respect, not merely on account of its intimate connection with historical knowledge, but also on account of the refinement and curious variety of the learning itself; which, grounded on merely imaginary principles, has been wrought into a system of the minutest accuracy. The best known English work on heraldry is that of *Gwillim*. The *Encyclopedia Heraldica* of Berry contains many modern additions. See also *Edmonson's complete Body of Heraldry*, 1780; *Dallaway's Inquiries*, 1783; and the article "Heraldry" in the *Enc. Metr.*, with the various authorities, English and foreign, there referred to.

HERBA'CEOUS (Lat. herba), in describing the texture of bodies, denotes their being green and cellular, as the tissue of membranous leaves. It is also applied to such perennial plants as lose their stems annually, while their roots remain permanent in the ground.

HERBA'RIA. (Lat. herba.) Collections of dried plants, such as the old botanists called *horti sicci* or dry gardens. They are formed by gluing to sheets of paper branches and other parts of plants pressed flat, and dried in the sun or otherwise. If well prepared, they are as useful to the botanist as plants alive; but it is necessary to have some practical skill to be able to employ them advantageously. The largest public herbaria are those of the Museum at Paris; the Imperial collection of Vienna; the Royal of Berlin; and that of the British Museum, formerly Sir Joseph Banks's. Nothing certain is known of the extent of these collections, but they probably contain in some cases as many as 60,000 species. The herbarium is an unattractive part of public museums; but a very important one for numerous purposes of science, both practical and speculative.

HE'RCULES. In Mythology, one of the most celebrated personages of antiquity, believed to be the son of Jupiter and Alcmæna. the daughter of Electryon, king of Mycenæ. The history and wonderful exploits of this hero are so well known, that it would be superfluous to dwell upon them here. There is, perhaps, no subject connected with antiquity to the right comprehension of which such formidable difficulties are presented; and hence the numerous attempts that have been made to separate truth from fiction in the history of Hercules, by divesting it of the mythological traditions with which it had been encumbered by all the writers of antiquity. In some shape or another, all the profane nations of antiquity seem to have possessed a divinity to whom they attributed an extraordinary degree of bodily strength, combined with indomitable perseverance and moral energy in prosecuting and overcoming difficult achievements. The reader will at once recognise, as belonging to this class, the Baal of the Syrians, the Melkarth of Phœnicia, and the Rama of Hindostan; who, like the Grecian Hercules, outstripping in bodily and intellectual endowments the great mass of the people of the rude era in which they lived, achieved a multiplicity of deeds which were looked upon as altogether miraculous, and which procured for their authors empire and dominion during their lives, and after death a place among the gods. (See *Müller's Dorians*, and the authorities there referred to.)

HE'RCULES. One of the old constellations in the northern hemisphere.

HE'RDERITE. (So called from Herder, who discovered it.) A mineral found in crystals embedded in fluor at Ehrenfriedensdorf, in Saxony; its primary form is a bright rhombic prism; its lustre is vitreo-resinous; and its specific gravity 2·985.

HEREDI'TAMENTS. In Law, all things which pass to the heir, being either corporeal (land, with those adjuncts which legally are comprised within that designation), or incorporeal, which are things collateral to land, or issuing out of it, and are enumerated in *Blackstone's Commentaries*, under the heads "Advowsons, Tithes, Commons, Ways, Offices, Dignities, Franchises, Crodies or Pensions, Annuities, and Rents."

HE'RESY. A word signifying the taking up of certain opinions in theological matters: from the Greek αἱρεσις, *choice*, which classical writers apply to the sects of philosophers. It is now confined to a theological sense, and is defined by Roman Catholic authorities to be the *voluntary* assumption and *obstinate* maintaining of error in matters of faith. They hold all error to be voluntary where the party knowingly deviates from the judgment of the church. The Protestants do not for the most part profess to have any certain standard by which men may judge whether their fellow men be heretical. We may infer from the directions of St. Paul to Titus that the nature of heresy was understood by the first preachers of Christianity; but it does not necessarily follow that any infallible tests should exist at the present day. It seems most consonant to a sense of human infirmity, and is the judgment of most divines of the Reformed persuasion, that those only should be considered as heretics by any community who maintain what are accounted by it erroneous opinions, either against their real convictions, or without condescending to listen to fair and reasonable argument, and in defiance of persons whose station, learning, and piety should entitle them at all events to attention.

HE'RIOT. In Law, originally a tribute given to the lord of the manor on occasion of his engaging in a war (here or heer-geld). In English law a heriot is a customary service, due for the most part on copyhold tenures, and termed heriot custom, being usually the best beast, whether horse, ox, or cow, that the tenant dies possessed of, which is due and payable to the lord of the manor. Some heriots, however, are due on reservation in a grant or lease of land; such are termed heriot service. In heriot custom the lord may seize the specific article which he seeks to recover; for heriot service he may either seize or distrain generally on the goods of the tenant on the land.

HERI'SSON. (Fr. *a hedgehog*.) In Fortification, a beam armed with iron spikes, and used as a barrier to block up a passage.

HE'RITABLE RIGHTS, in Scottish Law, comprehend in general rights to land and things connected with land which pass to the heir; the distinction being in most practical respects merely identical with that of English law between realty and personalty. Heritable jurisdictions were grants of criminal jurisdiction bestowed on great families by the crown. They were abolished after the rebellion of 1745 by the act 20 G. 2. c. 40.

HE'RMES. *See* MERCURY. TRISMEGISTUS.

HERMA'PHRODITE. (Gr.; from the well-known mythological fable of the union or confluence of the bodies of the nymph Salmacis and Hermaphroditos, the son of Ἑρμης, Mercury, and Αφροδιτη, Venus.) An organized body, in which there is either a real or apparent combination of the characteristics of the two sexes. The first is the "true," the second the "spurious" hermaphrodite. Hermaphrodites are also "natural" or "preternatural."

The animals in which the organs of the two sexes are naturally combined in the same individual are confined to the invertebrate division, and are most common in the

Molluscous and Radiate classes. If the term hermaphrodite may be applied to those species which propagate without the concourse of the sexes, but in which no male organ can be detected, as well as to those in which both male and female organs are present in the same body, then there may be distinguished three kinds of hermaphroditism.

First, The *Cryptandrous*, or in which the female or productive organs are alone developed. — Ex: The cystic Entozoa, the hydrostatic Acalephes, some Polypes, and Sponges.

Second, The *Heautanarous*, or in which the male organs are developed, but so disposed as to fecundate the ova of the same individual. — Ex.: The Cirripeds, the Rotifers, the trematode and cestoid Entozoa, and some Acephala, as the *Cyclas*.

Third, The *Allotriandrous*, or in which the male organs are so disposed as not to fecundate the ova of the same body, but where the concourse of two individuals is required, notwithstanding the co-existence in each of the organs of the two sexes. — Ex.: The gastropodous Mollusks, with the exception of the Pectinibranchiate order, and class *Annellida*.

All the other invertebrates, as the Cephalopods and pectinibranchiate Gastropods, most of the acephalous Mollusks, the insects, Arachnidans and Crustaceans, the Epizoa and the nematoid Entozoa, the Echinoderms and Medusæ, are, like the vertebrate classes, diœcious, or composed of male and female individuals.

The unnatural hermaphrodites may be divided into those in which the parts peculiar to the two sexes are blended together in different proportions, and the whole body participates of a neutral character, tending towards the male and female as the respective organs predominate; and into those in which the male and female organs occupy respectively separate halves of the body, and impress on each lateral moiety the characteristics of the sex.

This latter and very singular kind of hermaphroditism has hitherto been found only in insects and Crustaceans. In the extracts from the Minute Book of the Linnæan Society, printed in the 14th volume of their *Transactions*, it is stated that Alexander Macleay, Esq., Sec.L.S., exhibited a curious specimen, showing that two Papiliones referred to distinct families by Fabricius are in reality the male and female of the same species. This specimen presented the forms and colours of both sexes, divided by a longitudinal line on the body; the right wings and side of the body being as in the male (*Papilio polycaon*, Fabr.), and the left as in the female (*Papilio laodocus*, Fabr.).

In *Loudon's Magazine of Natural History* (vol. iv. p. 434.), an experienced entomologist, Mr. J. O. Westwood, has given descriptions and figures, not only of dimidiate hermaphrodites (the example is the *Bombyx penii*), but also of quartered hermaphrodites. The latter singular condition is exemplified in a specimen of the *Bombyx castrensis*, in which the right wing, left antenna, and left side of the abdomen are male; the left wing, right antenna, and right side of the abdomen are female: and again in a specimen of stag-beetle (*Lucanus cervus*), in which the left jaw and right elytrum are masculine, and the right jaw and left elytrum feminine.

In most dimidiate hermaphrodites the left side is masculine; but an example of the contrary has been observed in *Sphinx populi*. It is to be regretted that the condition of the internal organs of generation cannot be ascertained in the above singular examples; but this deficiency is in some degree supplied by the results of Dr. Nicholl's dissection of an hermaphrodite lobster (*Philos. Trans.* xxxvi. p. 290.), in which a testis was found on that side of the body which exhibited externally the male characteristics, and an ovarium on the opposite side.

In Botany, hermaphroditism is the rule, and a separation of sexes the exception, in the structure of flowers or reproductive organs.

HERME'TIC ART. The imaginary art or science of alchemy; so termed from Hermes Trismegistus, a personage of questionable reality, looked up to by the alchemists as the founder of their art. Some spurious works bearing his name are still extant. *See* ALCHEMY.

HERME'TIC SEAL. When a vessel or tube is perfectly closed by fusing its mouth or extremity, it is said to be *hermetically sealed*.

HE'RMITS, or E'REMITES. (Gr. ἐϱημος, *desert.*) Persons who, in the early ages of Christianity, secluded themselves from the world for devotional purposes, betaking themselves to solitary and desert places (ἐϱημός), whence their name. In the first five centuries of our era this class of persons was extremely numerous; nor have individuals been wanting in later ages who have undergone the same privations with the same mistaken views, and have acquired great reputation for sanctity in consequence. (See *Gieseler's Text Book*, vol. i.; *Riddle's Christian Antiquities*, 1839, p. 743.; *Heribertus, Vitæ Patrum et Eremitarum*, 1628; *Cavacius, Illustrium Anachoretarum Elogia*, 1625; *Enc. Metropolitana.*)

HERMODA'CTYLS. (Gr. Hermes, a river in Asia, and dactylus, *a date:* or from Εϱμης, *Mercury*, and δακτυλος, *finger;* i. e. *the fingers of Mercury.*) This term has long been applied to a species of colchicum tuber, probably that of the *Colchicum Illyricum:* it is irregularly heart-shaped, and has a furrow upon one side, not unlike the tuber of the *Colchicum autumnale*, now so much used in the cure of gout: it is imported from Turkey, and was formerly esteemed as a cathartic. Some of the old writers who are fond of the doctrine of signatures, compare the shape of the hermodactyl to that of a gouty finger, and have recommended its efficacy in that disease.

HERNANDIA'CEÆ. (Hernandia, one of the genera.) A small natural order of arborescent Exogens, inhabiting the Indian Archipelago and Guinea. They are very near *Thymelaceæ*, differing only in their fibrous drupaceous fruit, lobed cotyledons and involucre; and are very different from *Lauraceæ* and *Myristicaceæ*, to which orders they have been referred. The leaves, stem, &c. are slightly purgative: the roots of *Hernandia* are antidotes to the Macassar poison, its juice is a depilatory, and its leaves make a good sort of tinder.

HE'RNIA. (Gr. ἑϱνος, *a branch.*) A rupture. The term is generally applied to a tumour arising from a protrusion of part of the intestines or omentum into a sac composed of peritoneum: the groin, or upper and fore part of the thigh, below Poupart's ligament, are common situations. Other viscera may also occasionally form hernial tumours. When the condition of the accident is such that the parts cannot be reduced or returned into the abdominal cavity, the hernia is said to be *strangulated*, and in that case the passage through the intestines is interrupted; there is sickness and constipation; and inflammation, and even mortification of the part ensue, unless by an operation the cause of the stricture is removed and the gut returned. What is termed *congenital hernia* is the protrusion of a portion of intestine along with the testicle in its descent through the abdominal ring into the scrotum. Where a rupture exists in early infancy, it is commonly referable to this cause. The surgical history of ruptures is a very complicated and extensive, but highly important subject: it has been ably illustrated by several eminent practitioners, who have published treatises upon their causes and treatment.

HE'RO. (Gr. ἡϱως.) Lennep derives it from the verb αϱω, *I lift.* But the root of it is probably to be found in the same original word which appears in the Latin herus, *master;* Germ. ari-mann; perhaps the Sanscrit sura. The heroes of the Greeks were deceased mortals to whom divine honours were paid. It is probable, indeed, that such was the origin of their gods themselves (*see* POLYTHEISM); but if so, hero worship was a secondary or added system, which grew up in a later age. The word "hero," in Homer, is simply synonymous with warrior; nor is there any trace (at least in the *Iliad*) of hero-worship. It seems to have commenced not long after the composition of that poem. The last to whom any honours approaching to divine seem to have been paid were the Athenians slain at Marathon. The heroic age, commonly so called in Grecian poetry, seems to have ended with the descendants of those who returned from Troy. (*Wachsmuth, Hist. Antiq. of the Greeks; Thirlwall's History of Greece*, chap. 5. *Carlyle's Hero Worship*)

HERO'DIANS. A sect existing among the Jews at the period of our Saviour's preaching. (See Matthew, c. xvi.; Mark, c. viii. v. 15.) Much doubt exists as to their history and tenets: some commentators, both ancient and modern, imagine that they were fanatics, who regarded Herod the Great as the Messiah; others, that they were a mere political party, attached to the family of Herod; while a third opinion (Bergier, *Dictionnaire de Théologie*) is, that they supported some innovations attempted by Herod in the religious observances of the country by the partial introduction of Pagan usages. (See *Milman's History of Christianity*, i. 311.)

HERO'IC VERSE, that appropriated to epic or heroic poetry: in Greek and Latin, the hexameter. In English, Italian, and German, the iambic of ten syllables, either with or without the additional short syllable. In French, the iambic of twelve syllables. *See* EPIC, HEXAMETER.

HE'RPES. (Gr. ἑϱπειν, *to creep.*) A cutaneous disease, consisting of clusters of minute vesicles generally containing a brownish or milky lymph: in about eight or ten days they scab off, and other crops appear. It is not limited to any part of the body, but is generally preceded by more or less fever and pain or irritation of the part. It is often called the *tetters*. Another form of it constitutes the *shingles*. These eruptions are sometimes confounded with erysipelas, from which they are distinguished by the want of tumefaction and considerable constitutional symptoms, and by the natural state of the skin between the crops of eruption: they are distinguished from some similar eruptions by the vesicular form of the cuticular elevations at their first appearance, by their regular progress, and limited duration.

HE'RPETO'LOGY. (Gr. ἑϱπετος, *a reptile;* λογος, *a*

discourse.) That branch of science which treats of the history of reptiles.

HE'RPETON. (Gr. ἑρπετος, *a reptile.*) A genus of serpents, allied to *Eryx;* and characterized by two soft prominences covered with scales which are appended to the muzzle. Botanists have a herpeton which is a section of *Viola*.

HE'RRING. (Germ. heer, *an army;* in reference to the great numbers in which the fishes so called appear, at stated seasons, along our coasts.) The name is commonly applied to two distinct but closely allied species of the genus *Clupea*, Linnæus: to the one Mr. Yarrell restricts the name of *Clupea harengus;* the other is denominated *Clupea Leachii*, in commemoration of the excellent naturalist who first appears to have beena ware that our coast produced a second species of herring.

The genus *Clupea* is so nearly allied to the genus *Salmo* that they are both included in the same natural family, under the name of *Halecoids*, by M. Agassiz; the principal external difference consists in the absence of the small adipose dorsal fin in the *Clupea.* But in the clupeoids, as in the salmon tribe, the upper maxillary as well as the intermaxillary bones enter into the formation of the mouth, and are both armed with teeth; the body is always covered with numerous scales; and, in the greater number of the herring tribe, there is an airbladder, and the duodenum is complicated with many *cœca*, or pyloric appendages.

The annual migration of the herring is not, as has been described, from one latitude to another, but simply from a deeper to a shallower part of the ocean. The common species, impelled by the stimulus of the increasing burthen of milt or row, quits the deeper recesses of the ocean, where it has passed the winter and spring months, and approaches the shallower water near the coasts, where the ova may be deposited, and impregnated with the requisite amount of heat, light, and oxygen for their development.

The common herring visits different parts of our coast in autumn, generally earlier on the southern than on the northern localities, and deposits its ova and spawn towards the end of October. In this state the fish are termed "shotten herring," and they retire from the shore into deep water.

Leach's herring has a different season of sexual migration. "It is found," says Mr. Yarrell, "heavy with roe at the end of January, which it does not deposit till the middle of February Its length is not more than seven inches and a half, and its depth near two inches."

During the long period in which the herring stays in deep water, the shoals occasionally travel so far as to appear at the next season of oviposition at a different part of the coast from that where they were previously abundant. Hence the herring has been described as a most capricious fish; and it is truly said, "that there is scarcely a fishing station round the British islands that has not experienced in the visits of this fish the greatest variations, both as to time and quantity, without any accountable reason.

Herrings are taken in drift nets, and during the night. The stretching of the nets in the daytime is forbidden, as it is supposed that the practice would alarm and drive away the shoal. The darkest nights, and a breeze that ruffles the surface of the water, are the circumstances which most favour the capture of the herring.

HERRING FISHERY. *See* FISHERIES.

HE'RRNHUT. (Ger. herr, *the Lord;* hut, *protection.*) An establishment in Upper Lusatia, comprising, it is said, at present 120 houses, and 1500 inhabitants, which was founded by a few Moravians about the year 1722, under the patronage of Count Zinzendorf. The principles of the society thus formed are seclusion from the world, the enjoyment of a contemplative life, and the possession of all goods in common. Its members are bound together, under the title of Moravian Brethren, by strict laws and observances. Accusations have been thrown out against them of their indulging, in their retirement, in many licentious practices; but it is certain that their industry supplies many of the markets of Germany with various useful and ornamental articles of handiwork; that their zeal has prompted them to establish affiliated societies in many parts of Europe and America; and that in religious matters they are neither extravagant themselves, nor intolerant of others. (See *Mosheim*, vol. vi.)

HERSE, HERSI'LLON. In Fortification, a lattice or portcullis armed with spikes, to block up a gateway, or impede the march of an enemy.

HER'THA (sometimes written Aertha, Aortha, and Eorthe). In German Mythology, the name generally assigned in modern times to the chief divinity of the ancient German and Scandinavian nations. She was worshipped under a variety of names, of which the chief were exactly analogous to those of Terra, Rhea, Cybele, and Ops, among the Greeks and Romans. Long before the Christian era the knowledge of Hertha appeared to have been extended over a great portion of northern Europe; for in his work, *De Moribus Germanorum*, c. 40., in which the reader will find a graphic description of the peculiarities of her worship, Tacitus speaks of the wonderful unanimity which tribes that had no other feature in common displayed in worshipping this goddess, whom he designates Herthus, or *Mother Earth.* Her chief sanctuary was situated, according to the same authority, in a sacred grove in an island of the ocean, *in insula oceani*, which, by some writers, has been supposed to be Riga, and by others Zetland or Heligoland; but no modern researches have been able accurately to fix its locality. A great deal of curious information upon this subject is to be found in *Grimm's Deutsche Mythologie*, chap. x.

HESPE'RIA. (Gr. Ἑσπερια, *Evening;* the name of the daughter of Atlas.) A genus of butterflies, now the type of a family, including several subgenera, to some of which belong the British species, eight or ten in number.

HESPE'RIDES. In Greek Mythology the daughters of Night, or the granddaughters of Hesperus the brother of Atlas, three or seven in number, possessors of the fabulous garden of golden fruit watched over by an enchanted dragon at the western extremities of the earth. Such at least is the most ordinary form of the fable, but it is very variously represented; and these varieties are collected by M. Massieu, in a very complete dissertation on the subject, in vol. iii. of the *Mémoires de l'Ac. des Inscrip. et Belles Lettres*. There are also some observations on the subject in vol. xviii. p. 54. There is a difference among the mythologists whether the treasures of the Hesperides were in reality *fruit* or *sheep*, the word μῆλα signifying either (*Diod. Sic.* lib. v.); but the former is the received form of the story among the poets. (*Ovid, Metam.* 4.; *Virg. Ecl.* 6.; *Apollon. Rhod.;* and in the well-known lines of Milton,

> Hesperus and his daughters three,
> Singing around the golden tree

and, the oldest of all, Hesiod,

> —— αἱς μηλα περην κλυτου Ωκεανοιο,
> χρυσεα καλα μελουσι, φεροντα τε δενδρεα καρπον.

Some have explained this pleasing fable by the groves of orange and lemon trees, known to the Greeks only in the western parts of Africa.

HESPERI'DIUM. In Botany, a many-celled, few-seeded, superior, indehiscent fruit, covered by a spongy separable rind; the cells easily separable from each other, and containing a mass of pulp, in which the seeds are embedded — example, the orange.

HE'SYCHASTS. (Gr. ἡσυχασται, from ἡσυχια, *quiet; Quietists.*) In Eccl. History, a singular class of fanatics, who were established in the 15th century in some of the Greek monasteries of Mount Athos. They pretended to have attained a perfect interior life of devotional repose by intense contemplation. One of their maxims, apparently derived from some of the strange practices of the Indian ascetics, directs the disciple to "raise his spirit above all vain and transient things, repose his head on his breast, and turn his eyes with his whole power of meditation upon his navel." Hence these visionaries derived the nickname of Ὀμφαλοψυχοι, or Umbilicarii: they were also termed Thaborites, from their notion respecting a divine light inhabiting the heart of the devotee. (*Waddington's Hist. of the Church*, chap. xxvi.)

HETÆ'RIA. (From the Greek ἑταιρεια, derived from ἑταιρος, *a companion.*) This word is frequently used by classical writers to signify an association of any description; thus the fraternities of the early Christians are called Hetæriæ. In modern times two celebrated associations among the modern Greeks have assumed the name. The first was the Hetæria of the Philomusoi, or Friends of the Muses; a society formed for the purposes of education, founded (it is said) by Capodistrias, about 1814: it established schools at Athens and Miliæ in Thessaly, and numbered at one time 80,000 associates. It was dissolved in 1821; but renewed in 1824, when Athens was in the hands of the Greeks. The more celebrated political Hetæria owes its foundation to the celebrated Rigas, who died in 1798. It was renewed about 1816, extended its ramifications through all Greece, and produced the Greek revolution, begun by Ypsilanti in 1821.

HETEROCE'PHALOUS. (Gr. ἑτερος, *various*, and κεφαλη, *a head.*) In Composite plants, when some flower heads are male and others female in the same individual.

HE'TEROCHRO'MOUS. (Gr. ἑτερος, and χρωμα, *colour.*) When in a flower-head the florets of the centre or disk are different in colour from those of the circumference or ray.

HE'TERODOX (Gr. ἑτερος, and δοξα, *opinion*), signifying a person who holds opinions different from some standard with which they are compared, is opposed in theological language to *orthodox*, one who holds the right opinion. The standard of orthodoxy, by which all heterodox opinions must be tried, resides, humanly speaking, in the judgment of each particular sect of believers. It is, however, generally allowed to represent the highest and strictest interpretation of the creeds which were received in the ancient church, and in England is conceded by

general consent to what is called the High Church party. The use of these terms is said to have come into fashion in England in the beginning of the last century, when there arose a party within the church who, from the laxity with which they interpreted its formulas, and the assumed liberality of the views they took of its nature and authority, were styled Latitudinarians. The High Church or Orthodox party, on the other hand, were those who pushed their opposition to these innovators to an extreme length, but contented themselves with branding the others with the title of Heterodox, as a milder term than that of heretical, to which they would probably have been subjected in earlier and more violent times.

HETERO'GAMOUS. (Gr. ἑτερος, and γαμος, *marriage.*) In Grasses, when the arrangement of the sexes is different in different spikelets from the same root, as in *Andropogon:* in Composite plants, where the florets are of different sexes in the same flower-head.

HE'TEROGE'NEOUS ATTRACTION. *See* AFFINITY, CHEMICAL.

HETEROGENEOUS QUANTITIES, in Mathematics, are such as are incapable of being compared together in respect of magnitude, as lines and surfaces, surfaces and solids, &c.

HETERO'GYNA. (Gr. ἑτερος, and γυνη *a female.*) A tribe of Aculeate Hymenoptera, in which the females are of different kinds; one fertile, the other infertile, called neuters, as the ants, *Formicidæ* and *Mutillidæ*. See those words.

HETEROME'RANS, *Heteromera.* (Gr. ἑτερος, and μηρος, *a leg.*) Signifying that the legs have a different structure from one another. The Coleopterous insects are so called which have five joints in the tarsus of the first and second pairs of legs, and only four joints in the tarsus of the third pair. Latreille divides this somewhat artificial section into four groups.

1. *Melasomes*, having the wing-covers hard, wings generally wanting, claws simple, and maxillæ with a hook. — Ex.: *Pimeliidæ, Blapsidæ, Tenebrionidæ.*

2. *Taxicornes*, having the wing-covers hard, wings present, antennæ perfoliate or clavate, claws simple, maxillæ without a hook. — Ex.: *Diaperidæ, Cossyphidæ.*

3. *Stenelytres*, having the wing-covers hard and contracted posteriorly, wings present, antennæ simple, claws simple or toothed. — Ex.: *Helopidæ, Cistelidæ,* &c.

4. *Trachelides*, having the wing-covers flexible, wings present, head inserted upon a neck, claws bifid. — Ex.: *Meloe, Mordella, Horia, Lagria,* &c.

HE'TEROPODS, *Heteropoda.* (Gr. ἑτερος, and πους, *foot.*) The name of an order of Gastropods, comprehending those which have the foot compressed, and in the form of a thin vertical fin; as in the *Carinaria.*

HETERO'PTERANS, *Heteroptera.* (Gr. ἑτερος, and πτερον, *a wing.*) The name of a section of Hemipterans, comprehending those in which the hemelytra terminate abruptly by a membranous appendage.

HETERO'SCII, or HETERO'SCIANS. (Gr. ἑτερος, *another*, and σκια, *shadow.*) An epithet applied by the ancient geographers to the inhabitants of the two temperate zones, because their shadows at mid-day are always projected in the same direction in respect of themselves, but in opposite directions in respect of each other; in one case to the north, and in the other to the south.

HETERO'TROPAL. (Gr. ἑτερος, and τρεπω, *I turn.*) A term applied to the embryo of a seed when the former lies across the latter; that is to say, neither pointing to its base nor apex.

HE'XACHORD. (Gr. ἑξ, and χορδη.) In Music, a progression of six notes, to which Guido attached the syllables *ut, re, mi, fa, sol, la.* The hexachord is also called a sixth; and is twofold, greater and less. The former is composed of two greater, two less tones, and one greater semitone, making five intervals; the latter of two greater tones, one lesser and two greater semitones.

HEXAE'DRON, or CUBE. (Gr. ἑξ, *six*, and ἑδρα, *seat.*) One of the five regular or Platonic solids, so called from its having *six* faces. The whole surface of a hexaedron is equal to 24 times the square of the radius of the inscribed sphere, and to 8 times the square of the radius of the circumscribed sphere. Its solid content is 8 times the cube of the inscribed sphere. The other four regular solids are the tetraedron or pyramid, the octaedron, the dodecaedron, and the icosaedron.

HE'XAGON. (Gr. ἑξ, and γωνια, *angle.*) In Geometry, a plane figure bounded by six straight lines. When these are equal, the hexagon is regular. The side of a regular hexagon is equal to the radius of its circumscribing circle, a property which has numerous useful applications. The area is equal to the square of the side multiplied into the constant number 2·598076; that is, into three times half the tangent of 60°.

HEXA'METER. (Gr. ἑξ, and μετρον, *measure.*) The most important species of verse used by the Greeks and Romans. It consisted of six feet, either dactyls or spondees, which might be used indifferently in any part of the verse; with two important exceptions, that the last foot must invariably be a spondee, and the last but one a dactyl. In some instances a spondee is introduced into the fifth foot, or last but one; a licence which, if judiciously used, gives an agreeable variety to the otherwise unbroken fall of the verse, which is thence termed *spondaic.* (*See* FOOT, CÆSURA.) Hexameter verse was employed on almost every topic to which poetry can be applied. In modern times several poets of France, England, and Germany have attempted to introduce this measure into the language of their respective countries. The few specimens we have seen of it in French appeared to us wholly unsuccessful. The little countenance given to the attempts made by Dr. Southey and others, to introduce it among ourselves is conclusive, we think, against its ever being generally adopted in England; but, on the other hand, it has been cultivated in Germany with great success, as the *Hermann and Dorothea* of Goethe, and many other examples that might be cited, abundantly prove. How admirably the spirit of this measure had been caught by the learned Voss, and transfused into his translation of the great Virgilian and Homeric poems, is known to every scholar; and a similar instance may be seen in a beautiful little poem in the same language, called *Hannchen und die Küchlein*, by Eberhard. The qualities and effect of the hexameter have been well described by Schiller in the following distich, of which we subjoin an excellent translation by Coleridge; who, by the way, we may state, was long supposed to be the original author: —

> Schwindelnd trägt er dich fort auf rastlos strömenden Wogen;
> Hinter dir siehst du, du siehst vor dir nur Himmel und Meer.

> Strongly it bears us along, in swelling and limitless billows;
> Nothing before and nothing behind but the sky and the ocean.

(See *Quart. Rev.* vol. xlii.; and *Edin. Rev.* vol. xxxv.)

HEXA'NDROUS. (Gr. ἑξ, and ανηρ, *a male.*) Any flower having six stamens.

HE'XAPLE. (Gr. ἑξ, and ἁπλοω, *I explain.*) The combination of six versions of the Old Testament by Origen is so called: viz., the Septuagint, Aquila, Theodotian, Symmachus, one found at Jericho, and another at Nicopolis. See BIBLICAL HISTORY, &c.

HE'XAPODS, *Hexapoda.* (Gr. ἑξ, and πους, *a foot.*) A name applied by Mr. Kirby to a sub-order of Apterous insects, including those which have not more than six legs.

HE'XASTYLE. (Gr. ἑξ, and στυλος, *a column.*) In Architecture, that species of temple or other building having six columns in front.

HIA'TUS. (Lat. *yawning, gaping.*) A word which has passed into several modern languages. In Diplomatics and Bibliography, it signifies a deficiency in the text of an author, as from a passage erased, worn out, &c. In Grammar and Prosody, it properly signifies the occurrence of a final vowel, followed immediately by the initial vowel of another word, without the suppression of either by an apostrophe. This, in Greek and Latin poetry, was only admissible in certain excepted cases; as where, in Greek, a final long vowel is succeeded by an initial short vowel, and becomes sometimes short by position; or in Latin, where the *cæsura* (*see* CÆSURA) gave an additional force to the first vowel, as in the celebrated line,

"Ter sunt conatī imponere Peliō Ossam,"

which affords an instance of both, the first hiatus being occasioned by the cæsura; the second, an imitation of the Greek prosody. In French the hiatus is carefully avoided: in English less so, although by the more accurate poets still regarded as a blemish, except in some instances where a long vowel is followed by a short one. The worst species of hiatus is where the same vowel sound is repeated.

HIBI'SCUS (for Hybriscus; Gr. ὑβρις, *haughtiness*). A genus of very handsome plants, belonging to the Malvaceous order, with unusually large and showy flowers. They are numerous in the tropics, where they generally form fine trees; but some of the species are only annual. Of the latter *H. trionum* is a commonly cultivated plant, known in the seed-shops under the name of *bladder katmia.* Very few of the species are of any interest. *H. Syriacus* is the *Althæa frutex* of shrubberies; *H. abelmoschus* yields the musk-seed of pharmacy; and *H. esculentus*, the *Gobbo* or *Ochro* of the tropics, bears seed-vessels abounding so much in mucilage as to be a common ingredient in the soups of the hotter climates of the world. *H. Rosa sinensis*, a Chinese plant, is remarkable for the property possessed by its flowers of dyeing black.

HIDA'LGO. A Spanish nobleman of the lower class; literally "hijo d'algo," son of somebody: in Portuguese, "fidalgo." It is absurdly derived by B. St. Vincent from "hijo de goto." The title is now obsolete.

HIDE. (Germ. haut.) This term is limited in commerce to the strong and thick skin of the horse, ox, and other large animals.

HIDE-BOUND. In Farriery, applied to a certain disease of cows and horses in which the skin adheres to their sides.

HIDE OF LAND. *See* HYDE.

HI'ERA PICRA. (Gr. ἱερος, *sacred*, and πικρος, *bitter.*) A compound of aloes and canella bark made into a powder with honey.

HI'ERARCHY (Gr. ἱερος, and αρχω, *I rule*), is a general term, comprehending the various ranks and orders of the sacred ministry, whether of angels, according to an ancient opinion, or of the pastors of the church of God upon earth.

HIEROGLY'PHICS. (Gr. ἱερος, *sacred*, and γλυφω, *I engrave*.) Sculpture-writing or picture-writing; *i.e.* the expression of a series of ideas by representations of visible objects. The name is more peculiarly applied to a species of writing in use among the ancient Egyptians. According to the system of Champollion, the hieroglyphical writing of the Egyptians consists of three different species of characters:—1. The hieroglyphic, properly so called, in which the representation of the object conveys the idea of the object itself; either entire, or in an abridged form. Many words were thus expressed, chiefly those denoting common visible objects. These are termed by Champollion figurative, and divided into *figurative proper*, *figurative conventional*, and *figurative abridged*. 2. The second class of hieroglyphical characters consists of those which represent ideas by images of visible objects, used as symbols; and these are generally employed in the expression of abstract ideas or complex modes: as, a *tumult*, represented by a man throwing arrows; *adoration*, by a censer containing incense, &c. In some of these the connection between the type and antitype is obvious; in others, it depends on associations which are not understood by us, and consequently cannot be traced. These characters are what the Greeks more peculiarly termed hieroglyphics: they are called by Champollion *symbolical*. 3. The third class consists of *phonetic characters*, in which the sign represents not an object but a sound. This, according to Champollion, was effected by the following device. The figure representing a letter was the likeness of some animal or other object of which the name began with that letter. Thus Champollion has constructed an alphabet of initials, in which the letter A is represented by an eagle, the initial letter of the Egyptian word "eagle" (Ahorn) being A; and so forth. Twenty-nine elementary sounds were thus represented. But the writer was not confined to the use of one representative of a letter only. At first sight it would appear that all objects, the initial of whose name was a particular letter, might be used to express that letter; but custom seems to have applied only a certain number of objects to this use: some letters have eighteen or nineteen known representatives, others six or seven. In selecting out of these, the writer seems to have been guided by notions of what was suitable in reference to the word which he was writing; as, for example, the S in the word Si, *son*, is commonly represented by the figure of a goose, on account, according to Horus Apollo, of the supposed attachment of that bird for its young. The honour of the recent progress made in the explanation of hieroglyphical writing is divided between the English orientalist Dr. Young, and the Frenchman Champollion; but the latter appears to have had no small share in the original discoveries, as well as to have carried the science to a high degree of cultivation. Besides the hieroglyphic character, the Egyptians used the *hieratic* and *demotic*, which were, both of them, conversions of the hieroglyphic into a kind of current hand: the latter nearly alphabetical. The most civilized people of America, the Mexicans, at the time of the Spanish conquest, had advanced as far as the discovery of hieroglyphical or picture writing, although they did not possess a written alphabet. The Chinese writing was, originally, wholly ideographic; *i.e.* expressing ideas by symbols (answering to the second class of Egyptian hieroglyphics, with some admixture of the first). But in process of time the greater part of the characters have become simply phonetic. (See Dr. Young's "Egypt" in the *Enc. Brit.*, and his "Account of Recent Discoveries," 1823; the works of Champollion; Jablonski, *Pantheon Ægyptiacum; Quart. Review*, vols. xliii. liii.; *Edinb. Rev.*, vol. xlv.; *Salt's Essays;* Seyffarth, *Rudimenta Hieroglyphices*, 1825.)

HIEROGRA'MMATISTS. (Literally *sacred writers*.) The name given to certain Egyptian priests whose duty it was to decipher hieroglyphics and preside over the religious services.

HIEROMNE'MON. (Gr. ἱερομνήμων, *an observer of sacrifices*.) In Ancient History, the title of one of the two deputies sent to each meeting of the Amphictyonic Council by each tribe composing that confederacy. His office was, as the name imports, to superintend the religious rites on the occasion.

HIERO'NYMITES, or JERONYMITES. An order so named from its patron St. Jerome. It originated in Spain, and comprehended religious of both sexes. The Hieronymite convents are usually in mountainous and solitary places, in imitation of the retreat of St. Jerome to his hermitage at Bethlehem.

HI'EROPHA'NTES. (Gr. ἱερος, and φαινω, *I show*.) The title of the priest who initiated candidates at the Eleusinian Mysteries. He was necessarily a citizen of Athens, and held the office for life; which was regarded as one of high religious importance. (*Meursius on the Eleus. Mysteries; Potter's Grecian Antiquities*, vol. i. *Mem. de l'Acad. des Inscr.* vol. xxi.)

HIGH CHURCH. In English History, an epithet usually applied to those opinions which tend to exalt the ecclesiastical power, and to the parties which embrace them. According to Burnet (*Times*, vol. ii. p. 249.), the term "high church party" began to be used about the year 1700. Those who belonged to it were at that time considered to be unfriendly to the settlement of the nation at the Revolution, and disposed to Jacobite principles. Under Queen Anne, high church principles were for a short time in the ascendency; but after the accession of George I., in 1715, it is difficult to point out any political party which has seriously embraced them. But in matters relating to the discipline of the church itself, a "high church" and a "low church" party, the former attaching more and the latter less value to ecclesiastical dignities and ordinances, have always existed in the establishment of England.

HIGH COMMISSION, COURT OF, in English History, was erected by 1 Eliz. c. 1. as an ecclesiastical tribunal, without power to fine or imprison. The commissioners seem, however, to have committed various arbitrary acts towards the end of that queen's reign. One of their warrants was declared of no authority in 42 Eliz. Under Charles I. it assumed enormous and illegal powers, becoming a court for the trial of all manner of offences which might be construed as ecclesiastical; and was one of the grievances complained of and abolished by the Long Parliament, 16 Car. 1.

HIGHGATE RESIN. A fossil resin discovered on cutting the road through Highgate Hill: it is embedded in the clay in detached nodules.

HI'GHNESS. A title first attributed to bishops; afterwards to European kings in general (succeeded by Majesty in the sixteenth century), afterwards to sovereign princes and their descendants. The title of "Royal Highness" was first assumed by the Duke of Orleans, brother of Louis XIII., in 1631; and it is now conferred on all royal princes and princesses, whether in the direct line of succession or not. The elector of Hesse Cassel and the grand dukes of Germany have also the title of *royal highness*. The children of the emperors of Russia and Austria, and their descendants, are styled *imperial highness;* and all other princes not included in the above category bear the title *serene highness*, which is a literal translation of the term *Durchlaucht*, by which they are addressed in Germany.

HIGHWAY. A highway is a way over which the public at large have a right of passage, and includes a horse road, or a mere footpath, as well as a carriage road. It was considered formerly that no way which did not lead to a market town was a highway; but it is now settled that any way common to all people, without distinction, is a highway. A public navigable river is also called a highway. The right of the public in a highway is, however, a right of passage over it, and nothing more. The soil itself, and all the profits upon it, as trees, or underneath it, as mines, minerals, &c., and also any strips of waste land lying between the highway and the lands adjoining it on either side, belong, in moieties, to the owners of such adjoining lands. But if such strips of waste land be contiguous to or communicate with an open common, they are then taken to be part of the common. A highway may originate from a continual user of land by the public in traversing it without interruption from the owner, or from an express dedication of it by him to their use. A much shorter period of user will establish a right in the public than a right in any private person to a way; the user in the former case being so open and notorious that the owner of the land may fairly be presumed to have had early notice of it, and to have assented to it by not opposing it. Accordingly, a public way may be acquired by an enjoyment for five or six years, although twenty years' enjoyment is necessary in the case of a private way. A highway may also take its origin from statute, or from necessity. A highway originates from necessity when the accustomed line of highway is out of repair so as to be impassable; in which case the public have a right to traverse the adjoining ground, even if it be sown with grain.

The duty of keeping highways in repair is cast by the common law upon the occupiers of lands in the parish generally; but particular persons may be liable to repair by prescription or tenure. They may also be liable in respect of inclosure; that is, if a highway be free from fences on either side, and the owner of the adjoining land chooses to fence it off from the highway, he will then be liable in respect of his enclosure, because he has thereby deprived the public of using his land as a way of necessity, in the event of the original highway becoming impassable for want of repair. The omission to repair on the part of the parish or party liable is an indictable offence, and may be punished accordingly. Various statutes regulate the mode in which the occupiers in a parish are to contribute labour, carts, and cattle, for the purpose of repairing highways, and to perform upon them what is therefore called statute duty. Surveyors, also, are annually appointed in furtherance of the same objects. Highways

are frequently placed by the legislature under the jurisdiction of trustees; such highways are popularly called "turnpike roads." If sufficient materials for the repair of roads cannot be found on the waste lands of a parish, the surveyors have authority to take them from the lands of any private person ("such lands not being a garden, yard, avenue to a house, lawn, park, paddock, or inclosed plantation, or inclosed wood, not exceeding one hundred acres in extent"), on making him satisfaction for the materials taken away and the damage done, to be ascertained by the justices at special sessions. Any expenses incurred by the above proceedings may be reimbursed to the surveyors by an assessment made upon the occupiers in the parish, under the authority of two justices.

The laws for the regulation of highways have recently been consolidated and amended by the 5 & 6 Will. 4. c. 50. By previous acts of parliament, and by the common law, the county at large were bound to repair a public bridge, and also the highways at the end of such bridge to the extent of 300 feet. The recent act provides that in future when any bridge shall be built which the county shall be liable to repair, "all highways leading to, passing over, and next adjoining to such bridge, shall be from time to time repaired by the parish, person, or body politic or corporate, or trustees of a turnpike road, who were by law before the erection of the bridge bound to repair the highway." A most important alteration has been effected by the same act with respect to the creation of highways by dedication. Formerly, as appears above, if land had been traversed as a way by the public for a few years without interruption, a highway was at once established, and the liability to repair it was cast upon the parish; but by this act no road is to be deemed a highway which the inhabitants of a parish shall be compellable to repair, unless the person proposing to dedicate it to the use of the public shall give three months' notice to the surveyor of the parish of his intention to dedicate such highway, and the inhabitants of the parish, in vestry assembled, shall deem it of sufficient utility to them to justify its being kept in repair at the expense of the parish. If the vestry shall not deem it of such utility, a magistrate, on the surveyor's application, is to summon the party proposing to dedicate the new highway to appear before the justices at special sessions, and the question as to its utility is to be determined at their discretion.

HIMA'NTOPUS. (Gr. ἱμας, *a thong*, and πους, *a foot:* the term Himantopodes is given by Pliny to certain birds remarkable for the slenderness of their legs.) The name is now restricted to a genus of *Grallæ*, or wading-birds, in which the legs are proportionally longer and more attenuated than in any other species: the bill is long and slender, depressed at the base, and compressed toward the tip, with the nasal groove extending half the length of the bill. This genus includes the British species called the common stilt, or longshanks (*Himantopus melanopterus*). It is an occasional visitor, and a rare bird.

HI'PPIDES. The name under which Latreille and Eichwald designate a family of the tribe of Macrourous Decapod Crustaceans, typified by the genus *Hippa*.

HI'PPOBO'SCA. (Gr. ἱππος, *a horse*, and βοσκω, *I feed.*) A genus of Dipterous insects belonging to the Viviparous section of the order, in which the young are not only excluded from the ovum, but undergo their first metamorphosis in the womb of the parent, and are brought forth in the pupa state. (*Pupipara*, Latr.; *Homaloptera*, Leach.) The genus is now the type of a numerous family (*Hippoboscidæ*), generally known by the name of "forest flies," and divided by recent entomologists into numerous subgenera. The horse-fly (*Hippobosca equina*) is the type of the family.

HIPPOCRATEACEÆ. (Hippocratea, one of the genera.) This is a small natural order of plants, distinguished from *Celustraceæ* by little except the flowers being triandrous, and the filaments broad at the base. There are no species of any general interest included in the order.

HIPPOCRE'NE. (Gr. ἱππος, and κρηνη, *a fountain.*) A celebrated fountain at the foot of Mount Helicon, supposed to have been produced by the horse Pegasus having struck his foot against the mountain. It was regarded in antiquity with peculiar veneration, as it was believed to be a favourite haunt of the Muses, and was consequently looked upon as one of the chief sources whence the poets drew their inspiration. *See* Muses, Pegasus.

HI'PPODROME. (Gr. ἱππος, and δρομος, *a course.*) In Ancient Architecture, a place appropriated by the Greeks to equestrian exercises, and in which the prizes were contended for. The most celebrated in antiquity of these was at Olympia, which was four leagues long and one in breadth. The term is still in use.

HIPPOPO'TAMUS. (Gr. ἱππος, and ποταμος, *a river.*) A genus of aquatic Pachyderms, represented at the present time by a single species (*Hippopotamus amphibius*, L.) which inhabits the rivers of Africa. The generic characters are four toes on all the feet, inclosed in small hoofs; six molar teeth on each side of both jaws; very large and strong canines, of which the upper ones are nearly straight, the lower ones curved, and working upon each other so as to produce a chisel-edge; four incisors in each jaw, the upper ones short and conical, and bent inwards towards the mouth; the under ones long, cylindrical, and pointing forwards. The hippopotamus lives during the daytime immerged in the waters of its native rivers, rising to the surface and protruding its nostrils for the purpose of breathing: it comes to the land to feed during the night. Remains of species of hippopotamus are found in the tertiary formations of Europe, one of which hardly exceeded the size of a hog. In the tertiary beds at the base of the Himalaya range, an extinct species of hippopotamus has been discovered which had six incisor teeth in each jaw.

HI'PPOPUS. (Gr. ἱππος, *a horse;* πους, *a foot.*) The name of a genus of Acephalous Mollusks, significative of the resemblance which their shell bears to the foot of a horse. The valves of this shell are equal, regular, but inequilateral and transverse; the hinge has two compressed unequal teeth; the ligament is marginal and external. The *Hippopi* belong to the family *Tridacnidæ* of the Lamarchian system; but are distinguished from the genus *Tridacna*, by having the posterior slope and lunule closed, or nearly so, and the inner margin dentated at that part. The spines which arm the ribs are tubular, and are never arched orva ulted. The type of the genus is the *Hippopus maculatus*, or spotted hippopus; the *Æstrea hippopus* of Linnæus.

HIPPU'RIC ACID. (Gr. ἱππος, and ουρον, *urine.*) A peculiar compound deposited from the urine of the horse when it is mixed with muriatic acid. It closely resembles and is sometimes substituted for *benzoic acid;* but it contains nitrogen, and its salts are distinct from the benzoates.

HI'PPURITES. A genus of extinct Mollusks, supposed to be bivalves, and referred to the extensive group called *Rudistes* by Lamarck. The principal valve of the present genus is of a sub-cylindrical or elongated conical form, traversed by one or more internal longitudinal ridges, and closed by a small sub-circular discoid valve like an operculum.

The *Hippurites* are characteristic of the rocks of the cretaceous era in the south of France, Spain, Greece, and other countries bordering the Mediterranean.

HIPS. (Sax. hype.) In Architecture, the inclined diagonal edges of a roof where the sides intersect; hence a hipped roof is one in which two sides at least must intersect.

HI'RCINE. (Lat. hircus, *a he-goat.*) A term applied by Chevreul to a liquid fatty matter which may be separated from mutton suet, and gives it a peculiar rank smell, resembling that emitted by the male goat at the period of the rut. When saponified, it produces *hircic acid.*

HI'RING AND SERVICE, in Law, constitute the relation between master and servant. The general rule with respect to hiring and service is, that if there be no special agreement, but a general one without mention of time, the hiring is for a year certain; if the servant continue in his employment beyond that year, a second year is implied, &c. Consequently, if a master dismiss a servant hired generally, the servant is entitled to wages for the current year, unless the dismissal be for such a cause as will legally absolve the master from his contract: *ex.g.* moral misconduct, or refusal to obey orders. But in the case of domestic servants the contract is, by general custom, dissoluble by a month's warning on either part, or payment of a month's wages

HI'RSUTE. (Lat. hirsutus, *bristly.*) In Zoology, when an animal or part is covered with long stiffish hairs thickly set.

HIRUDINEÆ. *See* Leech.

HIRU'NDO. (Lat. hirundo, *a swallow.*) A genus which forms the type of the Fissirostral or wide-gaping Passerine birds of the Cuvierian system. It is now divided into the subgenera *Cypselus*, including the swift and *Hirundo* proper, embracing the chimney swallow (*Hirundo rustica*), sand martin (*Hirundo viparia*), &c. Our British species are occasional visitors, and the heralds, generally speaking, of the summer season, though we see now and then a premature straggler, which has given rise to the proverb "one swallow does not make a summer." Africa appears to be the chief resort of the British species during the winter season. Their disappearance at this season has, it is true, been accounted for on the hypothesis that the swallows passed the winter in a torpid state, submerged in river-heads or other fresh waters. No warm-blooded and quick-breathing animal does or can hybernate under water; and with respect to a bird, it is sufficient to observe that its extra-vascular plumage would be destroyed and decomposed by a six months' immersion. Swallows, like the cuckoo, immigrate to us for the purpose of breeding.

HI'SPID. (Lat. hispidus, *rough.*) In Botany, a term used in describing the superficial appendages of bodies, to denote their being covered with long rigid hairs, as the stem of *Echium vulgare.*

Hi'spid. In Zoology, when a surface is rough from minute spines or very rigid bristles.

HI'STER. A Linnæan genus of Coleopterous insects, now raised to a family (*Histeridæ*), belonging to the section *Pentamera*, and the subsection *Clavicornes* of Latreille. Many of the species of this family are remarkable for the instinctive promptitude and perfection with which they alter their ordinary appearance when alarmed, by drawing in their antennæ and folding up their legs, so as to feign death, and in many cases to take on the resemblance of a small black pebble or seed; whence one of the species is called *Seminulum*. It is this habit which probably suggested the generic name, from *histrio*, an actor. There are about fifty known British species referable to the Linnæan genus, and now divided into the subgenera *Abræus*, *Orithophilus*, *Dendrophilus*, *Platysoma*, and *Hister* proper.

HISTO'RICAL PAINTING. In Painting, that department of the art which comprehends all representations whereof history furnishes the subject. But under this head are generally included subjects from fabulous history, and those founded on allegory.

HISTORIO'GRAPHER. (Gr.) A professed historian, or writer of histories. It has been a common, although not uniform practice in European courts, to confer the place of public historiographer on some learned man as a mark of royal favour. Voltaire had at one period the title of Royal Historiographer of France.

HI'STORY. (Gr. ἱστορία, from the verb ἱστορέω, *I inquire*.) This word is first used in the commencement of the work of Herodotus, which he there calls by the title Historia. It is probable that this ancient writer thus fixed the sense in which the word has ever since been used,—as applicable, strictly and properly, to the civil history of man, although it has been analogically used to express other branches of investigation, as in the term Natural History, still in use; an application also sanctioned by classical usage, in the instances of *Theophrastus's History of Plants*, *Aristotle's History of Animals*, &c.

Civil history, properly so called, has also been subdivided into several branches: first, according to the class of events or actions which is made the subject of narration; as ecclesiastical, political, and literary: secondly, according to the extent of the subject; as universal history, in contradistinction to the history of particular nations or districts, or of individual men, more properly tern ed biography.

Our most ancient civil history is to be found in the Old Testament. But its objects are confined, after the brief and introductory narration of the first ages of the world, to the annals of a separate and peculiar people, the Jews, and such incidental notices of the affairs of other nations (Assyrians, Phœnicians, Egyptians, &c.) as the inspired writers found necessary for the illustration of their main topic. But the great empires and kingdoms which surrounded the little commonwealth of the Hebrews were also connected, by various circumstances of religion and descent, with the first of the two nations (Greek and Roman) whose annals constitute what is termed classical history, with which again our own history, or that of modern Europe, is in intimate association. Hence, in a general view of civil history, the whole subject may perhaps not be unappropriately classed under five heads; indicating, as it were, five different bodies of history, which in the main are distinct from each other in the subject, and partly in the sources from whence our knowledge is derived, although mutually throwing much light on each other.

I. The Jewish history, as contained in the Old Testament.

II. The history of the empires and states of antiquity in that portion of the world known to the classical and Jewish historians, and illustrated by classical and Jewish history; viz. Assyria, Persia, Egypt, Phœnicia, and its colony Carthage.

III. Classical history, properly so called; the history of the national affairs and conquests of the Greeks and Romans.

IV. The history of those nations and states (chiefly oriental) which possess annals of their own, independent of classical, Jewish, and modern European literature; China, India, modern Persia, Arabia, and the Mohammedan conquests.

V. Modern European history, including that of the colonies and conquests of Europeans.

1. The Jewish history, as we have said, is to be found in the Old Testament, some Apocryphal books, and in the writings of uninspired Jewish authors (Josephus and Philo-Judæus) who have investigated the antiquities of their country.

2. Of Assyria, Egypt, Phœnicia, ancient Persia, Carthage, &c., we possess no historical notice except such as is derived, 1. From Jewish or classical authors; 2. From monuments, especially in Egypt. Phœnician historical authors of repute (Sanchoniatho, Berosus, &c.) are alluded to by classical writers, and perhaps in part abridged by them; but we have no actual remains of their compositions on the authenticity of which reliance can be placed. With respect to Persia, much industry has been expended in endeavouring to extract from the histories of modern native writers coincidences with the narrations of Greek and Roman authors, but hitherto with little success.

3. The poems of Homer are generally regarded as containing the oldest fragments of Grecian history. Herodotus is the oldest Greek prose writer. His invaluable history comprises a description of several countries bordering on Greece and the Mediterranean; concise narratives of Egyptian, Persian, and Assyrian history; and a connected account, more or less detailed, according to circumstances, of the history of Greece, both civil and domestic, for about fifty years previous to the invasion of Xerxes, with which his annals close. (B. C. about 480.) The history of the Grecian commonwealth is pursued in detail by Thucydides and Xenophon for about a century afterwards. After that period our knowledge of Greek domestic history is confined to the incidental notices derived from various cotemporary writers, and the general compilations of later historians. Among these may be mentioned, as authors from whom a large portion of our actual knowledge is derived, Diodorus Siculus, the author of a very miscellaneous general history, of which great part is lost, who lived about the age of Augustus; Polybius, whose history is more especially devoted to Roman affairs; Arrian and Quintus Curtius, the historians of the conquests of Alexander; Livy, as to the transactions between Greece and Rome; Justin, the compiler of a brief but useful abridgment of general history; Plutarch, in his Lives of Illustrious Men, &c. These writers bring the student down to the period of the subjugation of Greece by Rome; after which all history of Greek affairs, properly so called, terminates, until the establishment of the Eastern empire, and we have little knowledge of the state of Greece and the Græco-Asiatic kingdoms in their provincial state.

Ancient Roman history, down to the first Punic War, is chiefly known from the compilations of Livy and Dionysius of Halicarnassus, writers whose credit is rendered extremely doubtful by modern investigation; and, where these fail, from incidental sources. In the History of the Punic Wars, the narrative of Livy is aided by the admirable work of Polybius. From the end of the second Punic War to the dictatorship of Sylla (nearly 150 years), our materials for Roman history are very deficient; the want of cotemporary writers being supplied only by later compilations, and by the incidental knowledge derived from writers on various subjects, the course of whose composition led them to touch on past events—of whom by far the most valuable is Cicero. From the period of Sylla's dictatorship to the accession of Vespasian (nearly 150 years), we have the advantage of a succession of cotemporary writers, some of them actors in the events which they describe, and comprising some of the greatest names in literature—Sallust, Cicero, Cæsar, Velleius Paterculus, Tacitus. Yet even here there is one considerable *lacuna*, comprising the last thirty years of the reign of Augustus, as to which our knowledge is scanty. From the accession of Vespasian to the reign of Constantine, a long period elapses during which our historical acquaintance with the events of an empire then comprising the greater part of the civilized world is vague and defective. Dio Cassius and Herodian are the two best writers on history who can be named in this long interval; the latter, during the short epoch which he illustrates as a cotemporary, is full and valuable. After the accession of Constantine, we have abundant materials for history, both ecclesiastical and civil, from the hand of cotemporary authors, down to the reign of Justinian in the East, and of Theodoric in the West, although the quality of the writers is sensibly degenerated. Perhaps the comparative obscurity and uncertainty into which history is plunged after the last of these two epochs, and the absence of all standard writers after Procopius, render it the best period to fix upon for the arbitrary limit between ancient and modern history. It will be seen from this brief summary that the only periods of any extent as to which we have the assistance of cotemporary historians (or original authority, properly so called), in the whole extent of classical history, are,—1. As to Greece, from B. C. 500 to B. C. 380.; 2. As to Rome, from the dictatorship of Sylla to the accession of Vespasian (B. C. 76 to A. D. 70); and, finally, the reigns of Constantine and his successors.

4. After the downfal of the Roman empire, a long series of revolutions in dynasties and nations followed before Western Europe was parcelled out into the several great countries which, notwithstanding all subsequent changes in political limits, have since subsisted as geographical divisions—Britain, France, Spain, Germany, Italy, the Scandinavian regions. Another period elapsed before the three great countries of Eastern Europe—Russia, Poland, Hungary—were added as distinct members to the family of European states; and the Greek empire in Europe remained apart, distinct in language,

manners, and political history, from both the other divisions.

From the fall of the Roman empire to the revival of literature (a period comprising in round numbers about eleven centuries) our knowledge of the affairs of Western Europe is derived from a series of writers, in each country, who are usually comprehended under the title of chroniclers. A chronicle, or book of annals, is properly a history of which the continuous narrative is so interrupted that each year forms a separate section, and events are thus related nearly in strict chronological order. This is a form very commonly adopted by the historians of the dark ages, of whom the greater proportion were monks, who appear to have noted down the acts which occurred within their own sphere of knowledge or memory, derived from the accounts of older men, merely to satisfy the vague desire of communicating knowledge to posterity, within the limited circle of the monastery or society to which they belonged. But a great many of the histories of the middle ages are not even in the form of chronicles; they have all the requisites which the most fastidious criticism can require of a regular history. Unity of purpose, and a sustained and energetic style, are qualities in which some of the early national annalists of modern Europe have been unsurpassed by their more instructed successors.

The Venerable Bede, who wrote in the 9th century, presents us with the first name of true credit and authority among the annalists of England. Of our monkish Latin chroniclers in later times, Matthew Paris is perhaps best entitled to the character of an historian. After the period of the invaluable Saxon chronicle, we have no English histories in the native language of the country worthy of note, with the exception of a few meagre rhyming chronicles, until the revival of letters and discovery of printing. In France, the long collection of native Latin chroniclers presents us with few names of interest after the time of the celebrated Gregory of Tours; but the Crusades called forth, for a short space, an unusual spirit of historical description. When we arrive, however, at the 14th and 15th centuries, we find among the native French historians two authors, Froissart and Philip de Comines, whose narratives are no less delightful from the talent and energy of the writers, than from the romantic character of the times which they pourtray. The annals of Italy are to be sought in the pages of a long series of chroniclers, from the 8th century downwards, of whom the most valuable are published together in Muratori's great collection. Their works are uniformly in Latin until the 13th century. But towards the end of that age the Tuscan dialect was elevated, as it were at a single step, to the rank of a literary language; and the little Tuscan republics produced a succession of historians, many of them remarkable for the purity of their style, and some (as the three Villani at Florence) for their extensive information and historical talent. Germany and Spain, in the middle ages, produced few historical works above the rank of dry chronicles. But the annals of the Scandinavian nations form the most important part of their early and peculiar literature. The Greek empire produced, also, a series of chroniclers, whose works have been collected in the *Corpus Historiæ Byzantinæ*.

The period of the revival of letters, and the following century, were distinguished by the appearance of several writers of first-rate merit in the department of history. In Italy, Guicciardini; in France, De Thou; in Spain, Herrera; and our own Camden may be added, not without justice, to the number. To follow the progress of history in modern times would be an impossible task. Suffice it to say, that with the advance of literary knowledge and the increase of education, historical writers seem to become more strongly divided into two very different classes: those who furnish contributions towards the history of their own times, especially the writers of memoirs, — a delightful and useful branch of literature, of which France gave the first examples, and still produces the most numerous; and the historians, more properly so called, who collect, discuss, and criticize, endeavouring to extricate the truth from the mass of former materials. The latter, in our times, has become more peculiarly the province of literary men. Philosophical history, in which the mere narrative of facts is regarded as subordinate to the elucidation of general truths, and too frequently to the establishment of favourite theories, is a modern improvement in the art; and Voltaire is commonly regarded, not without some truth, as the founder of the school of philosophical historians, among whom the highest rank in popularity has been attained and deserved by Gibbon.

5. The history of the more remote oriental nations, and also of those which derive their religion and civilization from Arabia, may be conveniently classed apart; because the knowledge of it is derived from wholly different sources, and requires, as it were, a peculiar education. Chinese and Indian history form two entirely distinct bodies of knowledge. With regard to that of the Mohammedan nations, it may be observed that it is brought into contact with that of modern Europe in several distinct countries and periods; of which the most remarkable instances are the Crusades, the annals of the Moors in Spain, and the history of the Turkish empire in its transactions first with the Greeks, and afterwards with the other nations of Christendom. It is a curious subject for the philosophical historian, and one which has not hitherto received the attention it merits, to compare the different accounts of the same events which have been transmitted to posterity by writers of distinct nations, religions, and languages, whose minds, from difference of education, habitually viewed almost every object in a totally different light.

HISTRIO'NIC ART. The art of acting in dramatic representations is not unfrequently so called, from the Lat. histrio, or hister, *an actor*. (*See* THEATRE.) The word histrio is of Etruscan derivation, as was the Roman dramatic art also. See *Mem. de l'Ac. des Inscr*. vol. xxvii.

HITCH. In Naval affairs, a particular kind of knot, of which there are several.

HITHE. An old Saxon word, signifying a port, wharf, or minor harbour, at which goods are shipped or landed: Queenhithe on the Thames is an example.

HOA'RY, in describing the superficial appendages of bodies, denotes their being covered with very short dense hairs, placed so closely as to give an appearance of whiteness to the surface from which they grow.

HO'BILERS (Lat. hobellarii), in England, were feudal tenants bound to serve as light horsemen, or bowmen; for the word seems to have been of somewhat uncertain employment. The smaller feudal gentry were long styled in France "Hobereaux."

HOE. In Agriculture and Gardening, an instrument for stirring the surface of the soil, cutting annual weeds up by the roots, and earthing up plants. The hand hoe is a thin plate of iron six or eight inches broad, and sharpened on the edge, fixed at right angles on the extremity of a pole or rod, which serves as a handle. This is called a draw hoe; because in the operation of hoeing the instrument is drawn or pulled towards the operator. Another description of garden hoe has the blade or iron plate fixed on the extremity of the handle, and in continuation of it: and this is called a thrust hoe; because in hoeing the operator always pushes the hoe forward. This kind is also called a Dutch hoe, most probably from having been first introduced from Holland. In agriculture there are hoes of the thrust kind drawn by beasts of labour, and commonly called horse hoes. In general form they resemble a plough; but instead of the share they have one or more iron blades, or plates with sharp edges, fixed to perpendicular iron rods at their lower extremities. These sharpened plates being drawn through the soil, cut through the roots of weeds an inch or two beneath the surface. Agricultural or field hoes are only used in the case of those field crops which are sown or planted in rows. There are a great many kinds of field or horse hoes; but it is worthy of remark that they differ very little in mechanical merit. The implement, indeed, does not seem susceptible of the same degree of improvement as the plough and the harrow.

HOEING. The operation of stirring the surface, cutting off weeds, or earthing up plants with a hoe. In the case of any of these operations dry weather must be chosen, otherwise the result will either be useless or injurious. Plants rooted up by the hoe in wet weather will produce fresh roots and grow again, while plants earthed up under similar circumstances will have the leaves which are covered by the soil decayed by it. In either case also, the ground will be hardened by the treading of the feet of men or horses, so as to obstruct the progress of the roots, and to exclude air and water from penetrating through it to them. Hoeing is sometimes performed on surfaces which are without weeds, for the purpose of stirring the soil; but in such cases pronged hoes, or hoes having three or more long spikes or teeth, are more effective than hoes with broad plates or blades.

HO'GSHEAD. An ancient measure of capacity, containing 63 old wine gallons.

HOLD. (Sax. healdan.) The inside of the bottom of the ship. It is divided into compartments by bulkheads across; and contains the ballast, water, coals and wood, provisions, and cargo.

HOLD. In Music, the same as PAUSE, which see.

HOLIDAYS, are considered to be those days, exclusive of Sundays, on which no regular public business is transacted at public offices. They are either fixed or variable, and vary in different public offices. The variable holidays are Ash Wednesday, Good Friday, Easter Monday and Tuesday, Holy Thursday, Whit Monday and Tuesday. *See* FERIÆ.

HO'LINESS. The title by which the Pope is addressed; equivalent to the Latin "Sanctissime."

HO'LING. (From hole.) In Architecture, piercing the plates to receive the nails.

HO'LING. Undermining beds of coal.

HOLM. (Sax. and Danish.) An island, or fenny place surrounded by water. Two well-known islands in the

Bristol Channel are called the Steep Holm, and Flat Holm.

HOLM OAK, or HOLLY OAK. *See* QUERCUS.

HO'LOCAUST. (Gr. ὅλος, *the whole*, and καίω, *I burn.*) A solemn sacrifice among the ancients, in which the whole of the victim was consumed upon the altar, in contradistinction to the usual custom which enjoined that only a portion thereof should be consumed. A similar custom prevailed among the Jews; it is called in Scripture a *burnt offering*.

HO'LOGRAPH. (Gr. ὁλόγραφον; from ὅλος, *whole*, and γράφω, *I write.*) In the Civil Law, a will written entirely by the hand of the testator.

HOLOTHU'RIANS. (Gr. ὁλοθούριον.) The name of the family of Echinoderms, having the genus *Holothuria* for its type. The body presents a subcylindrical elongated form; is defended by a coriaceous not spiny integument, open at both ends, and perforated by numerous small canals, in linear series, through which prehensile and adhesive suckers are protruded. At the anterior extremity is the mouth, surrounded with complicated retractile tentacula. At the opposite end is the aperture of the cloaca, in which the rectum and a respiratory branched tube terminate. The intestine is very long, and convoluted; and it frequently happens that when the animal is disturbed, it is protruded from the body or ruptured by the violenee of the contraction of the muscular parietes of the abdomen. The "trepang" of Eastern commerce is a dried species of *Holothuria*.

HOLT. (Sax. *a wood;* Germ. holz.) The termination of many names of places in England, derived from their ancient situation in a wood.

HO'LY ALLIANCE, THE. A league formed between certain of the principal sovereigns of Europe, after the defeat of Napoleon at Waterloo: on the proposal, it is said, of the Emperor Alexander. It arose from the religious enthusiasm which was prevalent at that period of deliverance from French domination, and with which the Russian emperor was just then considerably imbued. The act of this alliance is said to have been sent in his handwriting to the Emperor of Austria and King of Prussia, and signed by them. It is not supposed that the original terms of the league were other than indefinite: for the maintenance of justice, religion, &c. in the name of the Gospel. But it was subsequently connected with the determination of those monarchs to support, in conjunction with England and France, existing governments throughout Europe, by the Declaration of November, 1819: afterwards, the congresses of Troppau, Laybach, and Verona established the character of the alliance; to which the war of France against Spain, in 1823, gave additional illustration. Since the secession of England and France, the alliance can scarcely be said to have any active existence. (See *Ed. Rev.* vol. xxxii. xxxix.)

HO'LY ROOD, or HOLY CROSS. A festival kept on the 14th of September, to commemorate the exaltation of the Holy Cross. It is from this circumstance that the royal palace in Edinburgh has derived its appellation.

HO'LY STONE. A stone used by hand, with sand, to scour the ship's decks. The large stone worked by ropes is called the *bear*. The sand is used with water; but it has long been a very general practice in the navy to use dry sand below: this is called *dry holy-stoning;* it is considered more healthy than using water frequently.

HO'LY THURSDAY, or ASCENSION DAY. In the Romish Calendar, the 39th day after Easter Sunday. A festival in commemoration of Christ's ascension.

HO'MÆOMERI'A. (Gr. ὁμοιομέρεια, *similarity of parts.*) The name given to the physical theory of Anaxagoras, a Grecian philosopher of Clazomenæ, who flourished in the fifth century B.C. According to this hypothesis every material substance is made up of infinitely small parts similar to itself. Hence the growth and nourishment of animals and vegetables was accounted for, by supposing the alimentary substance to be analysed into its various component parts corresponding to the parts of the substance nourished. For instance, corn was supposed to contain particles of blood, bone, flesh, skin, &c., which by the process of digestion were separated from each other, and added to the corresponding parts of the animal body. This theory bears some resemblance to that of the *monads* of Leibnitz in modern times. *See* MONAD.

HO'MÆOPATHY. (Gr. ὅμοιος *similar;* and πάθος, *feeling or affection.*) The homæopathic method of healing diseases was first proposed by Samuel Hahnemann, a German physician, in 1796. It consists in the administration of medicines which are presumed to excite in healthy persons symptoms similar to those of the disease which is to be treated, upon the principle that *similia similibus curantur*. Thus they maintain that sulphur produces a pustular eruption upon the skin, and therefore cures pustular eruptions; and that quinia produces febrile symptoms, and therefore cures agues, and so forth. Not the least absurd part of this practice is the smallness of the doses in which the homæopathic remedies are administered, it being presumed that by infinite subdivisions the virtues of remedies are proportionately refined and exalted. A grain, for instance, of any active remedy, such as aloes, is triturated with 1000 grains of sugar of milk; when this mixture is complete, a grain of it is again diluted with 1000 of the vehicle; and so of medicines which the ordinary practitioner administers in doses of one or two grains or more, the homæopathist prescribes in the quantity of a millionth or the decillionth of a grain, or even less. Hahnemann was also a believer in animal magnetism. It is not surprising that enthusiasts of this cast should occasionally start up; but it is remarkable that they should find converts among persons in their right senses.

HO'MAGE. (Lat. homagium, or hominium, from homo, *man*, the usual term by which the vassal or dependant of a prince is designated in the older writers of the middle ages.) The symbolical acknowledgment of dependence due from a vassal to a feudal lord or superior when invested with a fief, or obtaining it by succession. In the earliest periods of he feudal system fealty and homage appear to be confounded (see *Sir F. Palgrave on the English Commonwealth*, vol. ii. p. cccxc.); but in later times the distinction was clearly established, and fealty might sometimes be due where homage was not. Homage was either homagium ligeum, *liege homage*, by which full and unreserved allegiance was rendered; or homagium non ligeum, *simple homage*, a mere acknowledgment of feudal superiority, with a saving or exception of the rights of other feudal lords. The one was personal, and could not be renounced (hence the doctrine of *allegiance*); the other bound the vassal only so long as he held the fief in respect of which it was due.

HO'MALIA'CEÆ. (Homalium, one of the genera.) A natural order of arborescent or shrubby Exogens, inhabiting the tropics. According to Brown related to *Passifloraceæ*, but distinguished by their inferior ovary. De Candolle places them between *Samydaceæ* and *Chailletiaceæ*. They are plants of some beauty, but of no known use.

HOME, in Naval language, is said of any thing that is close in its place; it is applied to the sheets of the sails, the shot and cartridge in a gun, and any article of stowage.

HO'MICIDE. (Lat. homo, *a human being*, and cædo, *I kill.*) In Law, the killing of any human creature; which is either justifiable — viz. 1. In case of necessity, public or private; 2. By permission of law for the advancement of justice; 3. For the prevention of forcible and atrocious crime. Or excusable — 1. By misadventure; 2. In self-defence on a sudden affray, or chance-medley. Or felonious: of which the species are — 1. Self-murder; 2. Manslaughter, which is defined "the unlawful killing of another without malice, express or implied;" 3. Murder, or the wilful killing of another by malice aforethought; 4. Petit treason, which by the Statute of Treasons was confined to the cases of a servant wilfully killing his master, a wife her husband, or an ecclesiastical person his superior; but the distinction in judgment between this offence and murder is now abolished.

HO'MILY (Gr. ὁμιλία, *an assemblage*), was used by the early fathers in the same sense as our word sermon; both of which, according to their original meaning, signify the familiar discourse with which the primitive teachers enforced their doctrines, in opposition to the more remote and declamatory orations which were more fashionable at the time. Up to the fifth century the practice of preaching was confined to the bishops, and the only homilies extant are of their composition. The term, which has now become obsolete, was in constant use as late as the Reformation; and the English Book of Homilies is a collection of plain sermons, setting forth the principal doctrines of Christianity, and pointing out the principles of Protestantism; of which the first part was published by Cranmer in the reign of Edward VI., and the second by order of convocation in that of Elizabeth.

HOMOCHRO'MOUS. (Gr. ὁμοῦ, *together*, and χρῶμα, *colour.*) When all the florets in the same flower-head are of the same colour.

HOMO'GAMOUS. (Gr. ὁμοῦ, and γάμος, *marriage.*) In Grasses, when all the florets of the spikelets of the same individual are hermaphrodite; in Composite plants, when all the florets of a flower-head are hermaphrodite.

HOMOGE'NEOUS. (Gr. ὁμοῦ, and γένος, *kind.*) Homogeneous bodies are those of which the constituent elements are all similar. Homogeneous quantities are such as can be added to or subtracted from each other.

HOMO'LOGOUS. (Gr. ὁμοῦ, and λόγος, *ratio.*) Having the same ratio or proportion. In Geometry, those sides of similar figures which are opposite to equal and corresponding angles are proportional to each other, and therefore said to be *homologous*. The areas and solid contents of such figures are likewise homologous for the same reason.

HOMO'NYMS. (Gr. ὁμοῦ, and ὄνομα, *a name.*) Words which agree in sound but differ in signification, as the substantive "bear" and the verb "bear."

HOMOOU'SIANS and HOMOIOU'SIANS. Names by which the Orthodox and Arian parties were distin-

guished in the great controversy upon the nature of Christ in the 4th century; the former word signifying that the nature of the Father and Son is the *same*, the latter that they are *similar*. (*Gibbon*, vol. iii. *See* ARIANS.) Homoousian (Gr. ὁμοουσιος) is derived from ὁμος, *the same*, and ουσια, *being*; Homoiousian (ὁμοιουσιος) from ὁμοιος, *similar*, and ουσια. (See also *Milman's Hist. of Christianity*, ii. 443.)

HOMOPHO'NOUS. (Gr. ὁμος, *the same*, and φωνη, *voice or tone*.) In Music, of the same pitch, or unisonal. Two or more sounds are said to be homophonous when they are of exactly the same pitch.

HOMO'PHONY. (Gr. ὁμος, and φωνεω, *I speak*.) Homophonous words or syllables, in language, are words or syllables having the same sound, although expressed in writing by various combinations of letters. Languages which abound in homophonies are, 1. Some Oriental monosyllabic tongues, namely, the Chinese and its kindred dialects, in which very few sounds comprise the whole vocabulary, and the same sound is expressed by a variety of ideographic characters (in Chinese there are only 400 such sounds, multiplied by the distinctions of tone and accent to 1600 or 2000); and, 2. Some European tongues in which, according to the genius of the dialect, the syllables of the original languages from which the words are chiefly derived have been contracted in speaking, and part of their sounds dropped, while the greater part of the letters is retained. Thus in English, and still more in French, which is peculiarly a dialect of Latin abounding in contractions, homophonies are numerous (in the latter tongue the number of syllables differently spelt, all having nearly the sound of our broad A, amounts to more than a hundred); while in Italian, in which the original proportions of the Roman language are preserved, they are scarcely to be found at all.

HOMO'PTERANS, *Homoptera*. (Gr. ὁμος, and πτερον, *a wing*.) The name of an order of insects, dismembered from the *Hemiptera* of Linnæus, including those in which the wing-covers are of an uniform semi-membranous consistency. Latreille divides this order into the three following divisions: viz.

1. The *Cicadariæ*, having the tarsi three-jointed, and the antennæ very short, terminated by a fine bristle.
2. The *Aphidiens*, having the tarsi two-jointed, and the antennæ longer, without a terminal bristle; containing the families *Aphidæ* and *Psyllidæ*.
3. The *Gallinsecta*, having the tarsi one-jointed, terminated by a single claw. The males have two wings, and are destitute of a mouth; the females are wingless, and furnished with a sucker.

HOMO'TROPAL. (Gr. ὁμος, and τρεπω, *I turn*.) In Botany, a term used in describing the direction of bodies, to denote any one having the same direction as the body to which it belongs, but not being straight.

HO'NEY. (Germ. honig.) A sweet viscid substance elaborated by the bee from the juices of the nectaries of flowers, and deposited in the waxen cells of the *honeycombs*. That which spontaneously runs out of the comb is called virgin honey. Pure honey consists of a syrup or uncrystallizable sugar, and of a solid or granular sugar which resembles that obtained from the grape.

HONEY STONE. A yellow mineral found in octoedral crystals at Artern in Thuringia. It is extremely rare. It consists of a peculiar acid (the mellitic acid) combined with alumina and water.

HONG. The Chinese name for the foreign factories situated at Canton. The hong merchants are those persons who are alone legally permitted to trade with foreigners. They are ten in number; and are always held responsible by the government for paying all duties, whether on imports or exports in foreign vessels. No foreign ship that enters the Chinese ports can commence unloading until she has obtained a hong merchant as security for the duties.

HONORA'RIUM. (Lat honos, *honour*.) A term used almost synonymously with *fee*, and applied at present chiefly to the fees tendered to professors in universities, and to medical or other professional gentlemen for their services. It was originally applied solely to the salaries of the great officers of state, whose services it was considered, by a perhaps pardonable euphemism, were remunerated only, as it were, *honoris causa*; a shade of meaning which is still perceptible in the present use of the term.

HO'NOUR (Lat.), in Law, signifies the more noble sort of seigniories, on which other lordships or manors depend by the performance of customary services.

The term *honour*, in its common sense, is susceptible of various significations; all of which, however, may easily be traced to its original meaning, *esteem or regard built on opinion*. Among the Romans honour was deified; and in modern times the term plays a no less important part, being used, in various terms of phraseology, to indicate certain rules by which society in general, and especially that portion of it called *fashionable*, has tacitly consented to regulate its proceedings, any deviation from which is attended by expulsion from its pale. To this class may be referred, with slight modifications of meaning, the phrases *debt of honour*, *law of honour*, *court of honour*, *affair of honour*, &c., which are all self-explanatory. The term was formerly the style of a man of rank generally; but it is now distinctively conferred on the Vice-chancellor, and the Master of the Rolls.

HO'NOURABLE. A title prefixed to the Christian names of the younger sons of earls, and to those of all the children, both sons and daughters, of viscounts and barons. It is also conferred on persons filling certain offices of trust and dignity, such as the maids of honour of the queen and queen dowager; and collectively on certain public bodies or institutions, as the House of Commons, the Congress of the United States, the East India Company, &c. &c. The title of *right honourable* is given to all peers and peeresses of the United Kingdom; to the eldest sons and all the daughters of peers above the rank of viscount; to all privy councillors; and to some civic functionaries, as the lord mayors of London and Dublin, the lord provosts of Edinburgh and Glasgow, &c.

HONOUR, LEGION OF. *See* LEGION, &c.

HOOPING COUGH. *See* WHOOPING COUGH.

HOP. The *Humulus lupulus* of Linnæus, the female flowers of which are used for imparting a bitter flavour to malt liquors for the purpose of preserving them from fermentation. The hop plant is a perennial indigenous to Britain and different parts of Europe; but to produce abundance of hops it requires to be very carefully cultivated in good soil, and even then is one of the most precarious of crops. The fields in which hops are grown are commonly called hop gardens: a loamy soil on a dry subsoil is chosen, and the plants are placed in hills, stools, or groups of three or four in a group, the hills being in rows five or six feet apart, and at about the same distance in the row. A full crop is not produced till the fourth or fifth year after planting. Every year the ground is dug in winter, and kept clear of weeds during summer; and the hills have poles, generally three or four to a hill, for the plants to twine on: the purchase of these poles, the fixing them in the soil every spring, the taking them down and stacking them every autumn, and their removal every five, six, eight, or ten years, according to the kind of wood used, constitute a considerable part of the expense of hop culture. The hops when mature are picked by hand, and as they are picked they are carried to a drying kiln, dried, and packed into bags or pockets; and this is also an expensive process. The hop plant is particularly liable to be injured by insects, by cold and continued rains, and by thunder storms; in consequence of which it is estimated that a full crop is not obtained oftener than above once in five years. Hence it is easy to conceive that the price of hops must vary greatly in different years, and that the grower who has a command of capital may profit largely by keeping them back from market when the prices are low, and only exposing them when they are high. In order to keep hops for two or three years, they require to be powerfully compressed, and put into much closer canvass bags than when they are to be sent immediately to market; they also require to be kept in dry airy lofts, neither too warm nor too cold. The culture of hops was introduced into England from Flanders in the reign of Henry VIII. The most extensive plantations are in Kent, Sussex, and Herefordshire; but they are cultivated to a considerable extent in many other counties. The hop growers are placed under the surveillance of the excise, a duty of 18*s*. 8*d*. per cwt. being charged upon all hops grown in this country. In 1837, the number of acres of land under cultivation of hops was 56,323; and in the same year the duty amounted to 310,794*l*. 4*s*., of which Kent contributed nearly one half.

HO'PLITES. (Gr. ὁπλιται, from ὁπλα, *arms*.) The heavy-armed infantry of Grecian antiquity. According to the Athenian regulations (similar probably to those of other states) the higher classes of citizens only, as estimated by the census, were liable to this expensive form of military service; in process of time, however, it seems that the Thetes or inferior classes also served as Hoplites. The Hoplites were armed in early times with the spear, heavy defensive armour, and large shield; the latter were exchanged after the time of Iphicrates for the light cuirass and target.

HOP OAST. A particular description of kiln used for drying hops. The floor of the kiln is generally of wire cloth, and the heat is generated in a stove with flues below. The hops after being put on the kiln are frequently turned, and in general they are rendered sufficiently dry in the course of a few hours; when dried they are taken to a loft and left to cool for a day or two, and then put into bags, having been previously subjected to the slight action of the fumes of burning sulphur (sulphurous acid), by which they are to a certain extent bleached.

HO'PPLE. A mode of fettering the legs of horses or other animals turned out to graze on a common or other unenclosed place.

HOP POLES, are poles or stakes annually inserted at the roots of hop plants for their stems to twine round. When a hop plantation is first made, as the plants are

weak the poles are not required to be more than five or six feet in length; but in the third or fourth year they require to be ten or twelve feet in length. Any kind of young trees or saplings may be used as hop poles; but the most durable are those of the oak, the ash, the sweet chestnut, and the larch. The locust or *Robinia* was strongly recommended as a durable hop pole by Cobbett; but though this wood is very durable when of not more than a certain age, it does not appear to be so when of the size most proper for hop poles. Much of the durability of the hop pole no doubt depends on the soil in which it is grown; but, all circumstances being alike, poles of larch wood, which are much employed in the neighbourhood of Farnham, have been found to last longer than any other.

HO'RARY CIRCLES, on Globes, are hour lines, or circles marking the hours, and drawn at the distance of 15° on the equator from each other. They are the same as *meridians*.

HO'RARY MOTION, is the motion of a celestial body, or the space which it moves through, in an hour. The apparent horary motion of the heavenly bodies in their diurnal revolution is 15°; for as the whole circle is completed in 24 hours, the 24th part of it, or 15°, must be passed over in one hour.

HORDE. A collective name given to those migratory nations who, like the Tartars, are not addicted to a pastoral life, but exist by plunder and rapine.

HO'RDEIN. A modification of starch, which, according to Proust, constitutes about 55 per cent. of barley-meal.

HO'RDEOLUM. (Lat. dim. of hordeum, *barley*.) A small tumour on the eyelid, somewhat resembling a barley-corn; it is a little boil projecting from the edge of the eyelid, and is commonly called a *stye*.

HO'REHOUND. This indigenous plant has a bitter and somewhat aromatic flavour, and is considered as an expectorant, and as giving relief in asthma; hence the celebrity of *horehound tea* among the common people.

HORI'ZON (Gr. ὁρίζω, *I bound* or *terminate*), in Astronomy and Geography, is the plane of a great circle of the sphere, dividing the visible from the invisible hemisphere. The horizon is either *sensible* or *rational*. The sensible horizon is a plane which is a tangent to the earth's surface at the place of the spectator, extended on all sides till it is bounded by the sky; the rational horizon is a plane parallel to the former, but passing through the centre of the earth. Both the sensible and rational horizon are relative terms, and change with every change of the spectator's position on the surface of the earth; in all cases they are perpendicular to the direction of gravity.

If the eye of the spectator were in the plane of the sensible horizon, stars would not appear to rise till they are above that plane; but if he is elevated above the horizon, a greater extent of the earth's surface will be visible, and the stars will appear to rise before they reach the plane which is a tangent of the earth. Hence the sensible horizon is sometimes defined to be the conical surface which has its apex in the eye of the spectator, and embraces that portion of the earth over which the eye can reach. The visual rays which are tangents to the earth are situated in this surface, and consequently point below the true sensible horizon, or the rational horizon which is parallel to it; and the angle which a visual ray makes with the plane of the horizon is technically called *the depression of the horizon*, or *the dip*. The dip can be easily computed from the known dimensions of the earth, and the height of the eye above its surface; but the real depression of a visible object below the horizon cannot be determined in this manner, on account of the refraction of the atmosphere, which prevents the rays of light from coming to the eye in a straight line.

HORIZO'NTAL RANGE, in Gunnery, is the distance to which a piece of ordnance will carry a ball on a horizontal plane. Supposing no resistance from the atmosphere, the greatest range would be when the piece is elevated at an angle of 45°; and in all other positions the horizontal range would be as the double of the sine of the angle of elevation. In a resisting medium the maximum horizontal range requires the elevation to be less than 45°. It is found by experience that with the ordinary velocity a cannon shot ranges the farthest when the elevation of the piece is about 30°. *See* GUNNERY.

HORN, partakes of the chemical nature of the cartilaginous part of bone; it consists chiefly of albumen, with some gelatine and a trace of phosphate of lime. *See* CORNUA.

HORN (commonly called French Horn). A brass musical wind instrument of a complex spiral form, increasing in diameter to its end or mouth, which the French call its *pavillon*. The inflexion of it is much regulated by the insertion of the hand in the pavillon.

HO'RNBLENDE. A mineral of a dark green or black colour, abounding in oxide of iron, and entering into the composition of several of the trap rocks. It is the *amphibole* of Hauy.

HORNBLENDE-SCHIST. A slaty variety of hornblende, generally including felspar and grains of quartz; it is of a dark green or black colour. Where clay slate is in contact with granite, it sometimes passes into hornblende slate.

HOR'NET. *See* VESPIDÆ.

HO'RNING, LETTERS OF In Scottish Law, a species of diligence (*i. e.* process) against a debtor. They are writs in the king's name, proceeding on the warrant of a decree of the Court of Session, or of the magistrates of boroughs, and of various other inferior authorities; but in these cases a warrant of the Court of Session must also be obtained. They direct the debt to be paid within a limited number of days (according to the nature of the debt). In default of such payment the debtor incurs the charge of rebellion, and is thereupon liable to *caption* or arrest.

HO'RNPIPE. The name of a well-known dance, for the skilful performance of which the British sailors have long been celebrated. The origin of the name is uncertain; but it is believed to be derived from a kind of musical instrument called *pib-corn* (Ang. *hornpipe*), consisting of a wooden tube with holes and a reed, and a horn at each end, which was formerly used in Wales. (See *Barrington's Archæologia*, vol. iii. 177.)

HORN SILVER. A name given by the older chemists to chloride of silver, which when fused puts on a horny appearance. For the same reason chloride of mercury or calomel is occasionally called *horn quicksilver;* and chloride of lead *horn lead.*

HO'RNSTONE. A variety of flint of a semitransparency somewhat resembling that of horn. One of the varieties of porphyry goes under the name of hornstone porphyry.

HORN WORK. In Fortification, a kind of outwork carrying on the head or fore part two demi-bastions resembling horns, whence the name.

HORO'GRAPHY. (Gr. ὥρα, *hour*, and γράφω, *I write.*) The art of drawing hour-lines, or of constructing dials.

HOROLO'GIUM, or HOROLOGE. (Gr. ὥρα, and λογος, *discourse.*) A term frequently used by ancient writers to denote a clock, watch, or other machine for measuring time.

HORO'LOGY (Gr. ὥρα, and λογος, *discourse*), signifies literally an explanation of the methods of measuring and marking the hours of the day. Anciently the term *horologium* was applied to any sort of contrivance for measuring the hours, as the clepsydra and sundial (see the terms); but as these instruments have been superseded by clocks and watches, horology is now usually understood to signify a description of the principles on which machines for the measurement of time, moved by weights or springs, are constructed.

Machines for measuring time are designated by the general appellation of *clocks* and *watches;* but they are also distinguished by peculiar names arising from certain modifications in their construction, or from certain particular purposes they are intended to serve. By the term *clock* is understood an instrument which not only shows, but also strikes, the hours. A *time-piece* is one which shows the hours without striking them; a *quarter-clock* is one which strikes the quarters as well as the hours; an *astronomical clock* is one which shows sidereal time; a *watch* is a portable or *pocket time-piece;* a *repeater* is one having a contrivance by means of which it can be made at any time to repeat the hours; a *chronometer* is a watch of the best kind, or one fit to be employed for astronomical purposes.

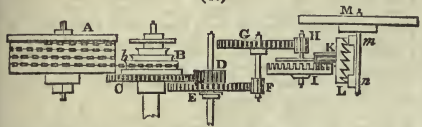
In a general view, horological machines may be regarded as consisting of three essential parts: — 1st, a moving power, which produces a rotatory motion about an axle; 2d, a train of wheel-work, by means of which a velocity is obtained having any required ratio to that of the primary axle; and 3d, a regulator, by which the rapidity of the revolution is determined, and uniformity of motion produced. The moving power is either a heavy weight which descends by the force of gravity, or a spring which is coiled up within a barrel and unwinds itself by the force of its elasticity; the first being preferred on account of the perfect regularity of its action when the instrument is to remain fixed in a place, and the second being necessary for pocket time-pieces and those which cannot be kept in a fixed position, as on ship-board. The train of wheel-work is chiefly remarkable on account of the delicacy and accuracy of its construction. The regulator is either a pendulum, of which, by the theory of falling bodies, the oscillations are isochronal or performed in equal times; or a heavy balance, the reciprocal vibrations of which are also isochronal. *See* BALANCE, PENDULUM.

Of the various mechanical contrivances introduced into horological machines for accomplishing particular purposes, it would be useless to attempt a description in this place, as our limits will not permit them to be given with that minuteness of detail which is indispensable in order to convey a clear idea of their action. The most important is the *escapement* (or scapement), or that part of the mechanism by which the original rotatory motion

is converted into a reciprocating motion, and gives impetus to the pendulum or balance. Some other parts are also of primary importance; as the *maintaining power*, a contrivance by means of which the motion is maintained, or the machine kept going, while the weight or spring is being wound up; the *fusee*, by which in watches and spring-clocks the force acting on the wheel-work is rendered equal in all states of the tension of the spring. *See* FUSEE.

The general arrangement of the wheel-work of a clock or watch may be understood from the following description. Fig. 1. represents the movement of a common

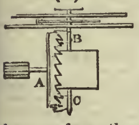
(1.)



vertical watch, the frame plates being omitted, and the dial being supposed to be turned downwards. A is the *barrel*, containing the spring which produces the motion. B is the *fusee*, connected with the barrel by the chain *b*. C is the *fusee-wheel*, called also the *first* or *great wheel*, which turns with the fusee, and works into the pinion D, called the *centre-wheel pinion:* this pinion, with the *centre wheel* or *second wheel* E, turns once in an hour. The centre wheel E works into the *third-wheel pinion* F; and on the same arbor is G, the *third wheel*, which drives the fourth or *centrate-wheel pinion* H, and along with it the *centrate wheel* I. The teeth of this wheel are placed at right angles to its plane, and act in the pinion K, called the *balance-wheel pinion;* L being the *balance-wheel*, or *scape-wheel*, or *crown-wheel*, attached to the same arbor. The balance-wheel acts on the two pallets *m* and *n* attached to the *verge* or arbor of the balance M; and these being placed at a distance from each other equal to the diameter of the balance-wheel, and in different planes, receive alternately from the scape-wheel an impetus in opposite directions which keeps up the vibratory motion of the balance.

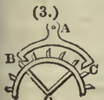
This last part of the mechanism, which it requires some attention to understand, is represented more distinctly in fig. 2., where A is the scape-wheel, and B and C the two pallets. The pallets, it is to be observed, are not placed on the verge in the same plane, but their planes form an angle equal to the excursion of the balance; so that, supposing one of them to be about 40 or 50 degrees from the mean point towards the right, the other is just as many degrees from the same point towards the left. The teeth of the scape-wheel are bent forward in the direction of the motion, like the teeth of a saw, and their number is odd. Suppose, now, a tooth of the scape-wheel to have caught the pallet B; it will continue to bear on that pallet, and to accelerate the balance, until, by the revolution of the verge, the extreme edge of the pallet comes into the plane of the extremities of the teeth, when the pallet escapes. But as the balance continues for a short time longer to move in the same direction, the pallet C now comes in between two teeth at the point diametrically opposite to the front of the tooth which B has just quitted; and as the vibration of the balance now commences in the opposite direction, this pallet is in its turn pressed upon and accelerated by the wheel.

(2.)



The *crown-wheel escapement*, now described, is the oldest and the original form, and is still used in common watches, where it answers sufficiently well; but when applied to clocks regulated by pendulums, it is exceedingly defective; for as it requires the vibration to be made in an arc of considerable extent, the pendulum must of necessity be short and light, and hence it becomes a very imperfect regulator. In order to obviate these defects, Clement, a London watchmaker, in 1680, invented the *crutch* or *anchor* escapement, which was greatly improved upon by Graham about the year 1700. Graham's escapement is represented in fig. 3. O is the centre of the scape-wheel. B A C, the crutch or anchor, consists of a heavy piece of metal attached to the rod of the pendulum with which it moves. A is its centre of motion; and in the original construction of Graham, the distance of A from O was equal to the diameter of the scape-wheel. The extremities of the crutch form the pallets, the acting faces of which are inclined planes; while the parts on which the teeth successively fall are cylindrical surfaces, the radii of which are equal to OA. The tooth being received on this surface, slides along it without tending to accelerate or retard the pendulum, until the pendulum arrives near the middle of its vibration, when the inclined plane comes to the extremity of the tooth, and the tooth then begins to act upon the plane, and to turn the pallets, and consequently accelerate the pendulum. By this arrangement the motion of the wheel only continues during the short time the tooth is sliding along the plane of the pallet, while during the rest of the vibration the tooth rests on the cylindrical surface, and the wheel stands still, or is *dead;* whence this escapement is called the *dead beat*, or the *escapement of repose*. In Hooke's form, where the cylindrical surfaces are wanting, the impulse given to one pallet carries the opposite with some force against the approaching tooth, and drives the wheel backward, or produces a recoil; and this force being applied at the extremities of the vibrations, tends greatly to disturb their isochronism. By Graham's method there is no recoil: the impetus is given while the pendulum is near the middle of the vibration, and the velocity the greatest; and during the rest of the vibration the pendulum is nearly altogether free of the action of the wheels.

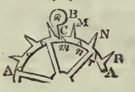
(3.)



Numerous other modifications of the crutch escapement have been proposed, and some of them carried successfully into effect; but for their description we must refer to the works in which the subject is technically treated. There are two, however, which, by reason of the greater ingenuity displayed in their contrivance, and their almost universal application to the best kinds of pocket watches, require particular notice. These are the *duplex* and the *detached* escapement, the latter being that which is used in modern chronometers.

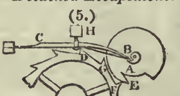
Duplex Escapement.—This is represented in fig. 4. A A is part of the scape-wheel, which is furnished with two sets of teeth, whence probably the name is derived. M N R are the teeth of repose, lying in the plane of the wheel; *m n r* are the teeth of impulse, and stand perpendicular to the plane of the wheel. B C is the impulse pallet, fixed upon the arbor of the balance just above the plane of the wheel, so that its extremity C may be caught by the teeth *m n r*, and receive the impulse from them, as they successively pass. A small ruby roller is also placed upon the arbor, behind the pallet, having a notch in one side of it for receiving the teeth M N R. When the tooth *m* has passed the claw of the pallet, the tooth M falls upon the ruby roller, where it rests until by the returning vibration of the balance the notch is brought to the point of the tooth. The tooth then falls into the notch, and thus passes the roller; and the next impulse tooth *n* comes up to the pallet, on the point of which it acts with great advantage in consequence of the long lever. As the successive impulses are all given in the same direction, the balance necessarily makes two vibrations for each impulse given by the upright tooth. The chief advantage of this construction consists in there being only one pallet, and in the action being independent of great accuracy in the execution of the teeth of the scape-wheel, which is indispensable in the case of the escapements already described, and also for the lever escapement, which in fact is only a modification of the crutch.

(4.)



Detached Escapement.— The annexed diagram, fig. 5., represents Earnshaw's construction. A is the main pallet projecting from the verge or arbor of the balance, concentric with which is another small pallet, called the *lifting pallet*, which, when the balance is vibrating from A towards B, lifts a very slender spring B, and with it the detent spring C, so as to set at liberty or unlock the tooth D, the point of which rests on a ruby pin projecting from the detent spring C, and forming the detent. The point E of the principal pallet having passed the tooth F, the wheel moves forward by the action of the main-spring, until the next tooth G falls upon the ruby pin and is locked. The screw H serves to adjust the position of the detent and the strength of the locking. In the return of the balance, the pallet A passes easily by the detent spring by forcing back the slender spring B. As in the case of the duplex, the balance here makes two vibrations for each impulse.

(5.)



Maintaining Power. — In order that a clock or watch, when perfectly regulated, may continue to indicate true mean time, it is necessary that it have some contrivance for continuing the action while it is wound up. Various methods of accomplishing this have been devised. One of the simplest consists in the interposition of a spring between the fusee and the wheel impelled by it, a little inferior in force to the main-spring (or weight), so as to remain always bent until the pressure of the main-spring is removed by the action of winding, when it begins to act upon a fixed point on one side and the wheel of the fusee on the other, so as to propel the work for a short time with a force nearly equal to that of the main-spring.

Some of the other parts of the mechanism, as the wheels for moving the minute and seconds hands, the

striking part of a clock, and the repeating part of a watch, though they form a considerable part of the bulk of the machine, require no great refinement of invention or dexterity of construction, and will be better understood from the inspection of a common clock and repeating watch than from any description which could be given.

The history of the invention of clocks is very imperfectly known. By some it has been ascribed to Pacificus, archdeacon of Verona, in the 9th century, and by others to Boethius in the early part of the 6th. The Saracens are supposed to have had clocks which were moved by weights as early as the 11th century; and as the term is applied by Dante to a machine which struck the hours, clocks must have been known in Italy about the end of the 13th or beginning of the 14th century. It is said that the first clock made in England was furnished out of the proceeds of a fine imposed upon the chief justice of the King's Bench in 1288, and that it remained in its original situation, in old Palace Yard, as late as the reign of Elizabeth. In the reign of Richard II. a large astronomical clock was made by Richard of Wallingford, abbot of St. Albans, which was regulated by a fly. But the most ancient clock of which we possess any certain account was erected in a tower of the palace of Charles V., king of France, about the year 1364, by Henry de Wyck or de Vick, a German artist. A clock was erected at Strasburg about 1370, at Courtray about the same period, and at Spire in 1395. In the following century public clocks appear to have existed in all the principal towns of Europe, and private ones to have come into very general use.

The earliest clocks were doubtless very rude and imperfect instruments, and their present state of excellence must have been attained by slow and successive improvements. Wheel work, set in motion by springs and weights, was known in the time of Archimedes; and in order to have a timepiece it was only necessary to apply some contrivance to regulate the motion. For this purpose recourse was first had to a fly wheel; but it would soon be found that the fly, the action of which depends on the resistance of the air, would form a very imperfect regulator. The clock of Henry de Wyck, above mentioned, was regulated by an alternating balance, which was formed by suspending two heavy weights from a horizontal bar fixed at right angles to an upright arbor, and the movement was accelerated or retarded by diminishing or increasing the distance of the weights from the arbor. It had no regulating spring, and the action may consequently be supposed to have been very irregular; nevertheless clocks regulated in this way were used for astronomical purposes by Walther, Tycho Brahe, Mœstlin, the landgrave of Hesse, and others. The capital improvement of the pendulum dates from about the middle of the 17th century; but it is very uncertain by whom the application was first made or proposed. Galileo was the first who remarked, or at least the first who formally announced, in his work on mechanics and motion, which was published in 1639, the isochronal property of oscillating bodies suspended by strings of the same length; and it has been pretended that he actually applied a pendulum to a clock for the purpose of observing eclipses and determining longitudes. There is, however, no proof of this fact, which has been strongly disputed. Sanctorius, in his *Commentary on Avicenna*, describes an instrument to which he had applied a pendulum in 1612. Richard Harris is said to have constructed, in 1641, a pendulum clock in London for the church of St. Paul's, Covent Garden. Vincenzo Galilei, a son of Galileo, is stated, on the authority of the *Academy del Cimento*, to have applied the pendulum in 1649. It was applied by Huygens in 1656; and by Hooke, for whom the invention has been claimed, about 1670. But to whomsoever the merit may belong of having first made the application, Huygens is unquestionably the first who accurately explained the theory of the pendulum; and hence, perhaps, the invention of the pendulum clock has been usually ascribed to him. Huygens demonstrated that the vibrations in circular arcs are not independent of the length of the arc, and that in order to obtain perfect isochronism, the ball of the pendulum must move in the arc of a cycloid; and, ingeniously applying a property of the cycloid, of which he was the discoverer, namely, that its involute is a curve similar to itself, he procured the requisite motion by causing the pendulum to vibrate between cycloidal cheeks about which the upper and flexible part of the suspending rod wrapped itself in its motion. But it was found that no practical advantage could be obtained from this beautiful contrivance; and in fact it was soon rendered unnecessary by the invention of the anchor escapement, which gives the means of rendering the arcs of vibration very small, in which case the error depending on the length of the arc becomes insensible. The application of the spiral spring to the balance is the undoubted invention of Hooke.

Another invention, which marks an epoch in the history of horology, is that of a method of counteracting the effect of changes of temperature on the pendulum rod and balance. The mercurial compensation pendulum was invented by Graham about the year 1715. Graham likewise suggested the method of effecting the compensation, by means of the unequal expansions of different metals; an idea which was subsequently realized by Harrison in the construction of the gridiron pendulum, which is now very generally used. The compensating apparatus in the watch balance depends upon the same principle, but the mechanical arrangement is necessarily very different. See BALANCE.

For full information on this subject the reader is referred to the following works:—Berthoud, *Essai sur l'Horlogerie;* Id., *Histoire de la Mésure du Tems; Cumming's Elements of Clock and Watch-Work; Derham's Artificial Clockmaker; Harrison's Principles of his Timekeeper; Earnshaw's Explanations of Timekeepers; Reid's Treatise on Clock and Watch-making;* the article "Horology" in the *Penny Cyclopedia*, &c.

HORO'METRY. (Gr. ὥρα, and μετρον, *measure.*) The art of measuring hours.

HO'ROSCOPE. (Gr. ὥρα, and σκοπεω, *I observe.*) A representation of the aspect of the heavens and positions of the celestial bodies at a particular moment, drawn according to the rules of the imaginary science of astrology. Thus the aspect of the heavens at the moment of the birth of an individual is his horoscope, and supposed to indicate his future destinies. See ASTROLOGY.

HO'RPOE. See UPUPA.

HORRIPILA'TION. (Lat. horror, and pilus, *a hair.*) The common expression of the "hair standing on end," implies the shuddering sensation to which medical writers often apply this term.

HORSE. See EQUUS.

HORSE. In Nautical affairs, a foot rope to support the feet of the seamen while leaning over a yard or boom to furl the sail. Also, a rod or rope along which the edge or the corner of a sail traverses by means of hanks.

HORSE POWER. This term, as applied to steam engines, refers to the weight which they are capable of raising to a given height in a given time. Watt estimated a single horse power at 32,000 pounds avoirdupois lifted to the height of one foot per minute; this is, however, nearly double the work of a single horse as usually applied to raising weights.

HORSE RA'DISH, the root of the *Cochlearia armoracia*, which when scraped is often eaten as a condiment and an ingredient in sauces, has a place in the *Materia Medica* as a stimulant, and a compound spirit and compound infusion are directed in the *Pharmacopœia:* the latter very soon becomes putrid, and neither are useful.

HORSE SHOE. In Fortification, a work of a round or oval form.

HO'RTICULTURE. (Lat. hortus, *a garden*, and colo, *I cultivate.*) The culture of the kitchen garden and orchard. In the kitchen garden are cultivated every description of root, herb, flower, and fruit, used in cookery; and in the orchard the more hardy fruits used in cookery, and in the dessert. The finer fruits are grown against espaliers, walls, hot walls, or under glass. The chief difference between horticulture and agriculture is, that in the former art the culture is performed by manual labour in a comparatively limited space called a garden; while in the latter it is performed jointly by human and animal labour in fields, or in an extensive tract of ground called a farm. See GARDENING, AGRICULTURE, and FARMING.

HO'RTUS SICCUS. A collection of dried plants preserved in books or papers.

HOSA'NNA. (Heb.) An exclamation, signifying literally *save now*. This Hebrew word occurs only once in the Old Test., viz. Psalm cxviii. 25. This psalm is the last of those which compose the "great Hallel.;" and hence, perhaps, this invocation was used by those who conducted our Saviour into Jerusalem. (Matt. xxi., Mark xi., John xii.) It was afterwards commonly adopted in the church. (*Riddle's Christian Antiquities*, p. 335.)

HOSIERY. See WOOLLEN MANUFACTURE.

HO'SPITAL. (Fr. hôpital.) In Architecture, a building raised and endowed for the reception of persons incapable of supporting themselves and procuring medical assistance, or as a refuge for the unfortunate or needy. Many of the charitable institutions in Great Britain are called hospitals; and are incorporated bodies, possessed of great wealth, which is expended in the support of schools, &c. (See *M'Culloch's Statistics; De Gerando, de la Bienfaisance publique*, vol. iv. book 3.)

HOSPITAL GANGRENE. A species of ulcerating gangrene, peculiarly characterized by its infectious nature, and its tendency to attack wounds or ulcers in crowded hospitals.

HO'SPITALLER, in its original acceptation, was applied to certain religious bodies, who held it their duty to provide lodging and entertainment for those persons engaged in pilgrimages. One of the most celebrated institutions of this kind was that at Jerusalem, which gave its name and origin to the Knights Hospitallers,—a well-

known religious body, instituted about the end of the 11th or the beginning of the 12th century. They soon afterwards settled permanently in England, and gradually attached a degree of wealth and importance unequalled in the history of similar bodies. They followed the rule of St. Austin, and wore a black habit with a white cross upon it. At their original institution they were styled Knights of St. John of Jerusalem; afterwards Knights of Rhodes, and again Knights of Malta; these two islands having been successively conferred on them by different monarchs. *See* St. John of Jerusalem, Knights of.

HOSPI'TIUM (Lat.), signifies in general a place or inn for the reception of strangers, in which sense it is used by old writers; but it is in modern times almost wholly restricted to the celebrated inns on St. Bernard and St. Gothard, in Switzerland, to which travellers to and from Italy resort.

HO'SPODAR, or WOIWODE. The lieutenants appointed by the Porte to govern the two Christian provinces of Moldavia and Wallachia are so called. By the treaty of Adrianople between Prussia and Turkey (1829), these officers are to hold their appointments for life, and to pay a fixed annual tribute.

HOST (from the Latin hostia, *a victim*), is applied in Theological language to the bread and wine under the appearance of which the Roman Catholics conceive the body and blood of Christ to be present upon the altar. The elevation of the Host is a ceremony prevalent in all Catholic countries, in which the consecrated elements are raised aloft and carried in procession through a church, or even through the streets of a city. On these occasions the people fall on their knees and worship the Host. The origin of the custom is dated from the 12th century, when, it is said, it was thought necessary to make this public and conspicuous declaration of the Eucharist on the occasion of the promulgation of the opinions of Berengarius against transubstantiation.

HO'STAGE. (Lat. hospes, *guest.*) A person left as surety for the performance of the articles of a treaty. The practice of taking hostages is now almost unknown in the mutual relations of civilized communities; but was formerly so common as to have given rise to many questions in the law of nations. Hostages were divided into principal and accessary; the latter being where it is expressly stipulated by treaty that the hostage shall be answerable for the event. One of the points debated among civilians on this subject was, whether such a hostage could lawfully stake his life, and whether in the event of his doing so it was lawful to take it. The affirmative was argued from the most ancient example of hostageship on record, — Reuben's words to Jacob, "slay my two sons if I bring not Benjamin back." According to Philip de Comines, the Liegois having given hostages to Charles Duke of Burgundy, with express power to put them to death in the event of an infraction of the treaty, and that event having taken place, it was much debated in the council whether the power should not be carried into execution; and after much discussion their lives were spared. It has also been questioned whether an hostage can be delivered up against his will: Grotius decides in the affirmative. The extent of the rights of conquerors over hostages, the events which may dissolve their obligation, the effect of their escape upon the convention between the principals, and other points of the subject, are treated at length by writers on national law.

HOTCHPOT, in Law, is a blending or mixing together of lands given in marriage with lands in fee falling by descent. As if A. had two daughters, and gives a third part of his lands in marriage with one of them to her husband, and dies seised of the other two thirds: in order to acquire any farther share of these lands, the married daughter must bring the lands first given into hotchpot; that is, she must renounce the gift, and allow the land to be confounded with the rest, in order that she may inherit her whole share; otherwise her sister will have the remaining two thirds of the lands. There is also a rule of hotchpot with respect to the distribution of personal property within the stat. 22 & 23 C. 2. c. 10.; as, where a certain sum is to be raised and paid to a daughter for her portion by a marriage settlement, if the daughter would have any further share of her father's personal estate she must bring this money into hotchpot, and allow it to form part of the distributable residue.

HOTE'L (Fr.), signifies, in a general sense, a large inn for the reception of strangers; but in a particular sense, especially in France, it is applied to the residences of the king, nobility, or other persons of rank: or it is used synonymously with hospital, as the *Hotel Dieu*, *Hotel des Invalides*, &c.

HO'THOUSE. A general term for the glass structures used in gardening, and including stoves, greenhouses, orangeries, and conservatories. Pits and frames are garden structures with glass roofs, with the sides and ends of masonry or wood; but they are generally so low as not to admit of being entered and walked in, and this seems to prevent them from being included under the term hothouse. *See* Stove, Greenhouse, Pits and Frames.

HOTWALL. In Gardening, walls for the growth of fruit trees, which are built with flues or other contrivances for being heated in severe weather, so as to facilitate the ripening of the wood or the maturity of the fruit. The most common form of hotwalls is that in which flues or tunnels are conducted through them, into which the smoke and heated air from fires are made to ascend from a furnace at the bottom of the wall to a chimney on the top; but in some cases hotwalls are formed by constructing the entire wall hollow, tying the two sides together by cross-stones or bricks, and introducing heat by means of pipes of metal containing steam or hot water along the bottom of the vacuity, the heat of which rises to the top of the wall, and heats every part in its progress. In all climates north of the meridian of London, hotwalls are of great use for ripening fruits and young shoots, and preserving tender plants. *See* Wall.

HOUNDS. In Naval Architecture, the projecting parts of the sides of the mast, near its head, which, like shoulders, support the rigging, &c.

HOUR, in its general acceptation, denotes the twenty-fourth part of a mean solar day, or of the time in which the earth makes a complete revolution in respect of the sun. The division of the artificial day, or time from sunrise to sunset, into twelve equal parts, belongs to the remotest ages of antiquity (see *Goguet, Origine des Loix, &c.*); the division of the *night* into the same number of parts was introduced at Rome in the time of the Punic wars. The Italians make the day commence at sunset, and reckon on to twenty-four hours, or to the succeeding sunset. Astronomers also reckon twenty-four hours from mid-day to mid-day; but in the civil reckoning only twelve hours are counted, namely, from midnight to midday, and from mid-day to midnight. The hours which result from the division of the artificial day into twelve parts are called *temporary hours*, from being of unequal lengths at the different seasons of the year.

HOUR CIRCLES, or HORARY CIRCLES. The same as meridians; being great circles of the sphere perpendicular to the equator, and their planes making with each other angles of fifteen degrees.

HOUR-GLASS. A species of chronometer or clepsydra, measuring intervals of time by the running of water or sand from one glass into another.

HOU'RIS. The name given by the Europeans to the imaginary beings whose company in the Mohammedan paradise is to form the principal felicity of the *believers.* The name is derived from hûr al oyûn, signifying *black-eyed.* They are represented in the Koran as most beautiful virgins, with complexions like rubies and pearls, and possessed of every intellectual and corporeal charm. They are not created of clay, as mortal women, but of pure musk; and are endowed with immortal youth, and immunity from the diseases and defects of ordinary beings. (See *Koran*, chap. 55, 56., Sale's translation; and the Prel. Discourse, s. 4.)

HOURS. (Gr. Ὧραι.) In Mythology, divinities regarded in two points of view—as the goddesses of the seasons, and hours of the day; and their number is stated in different ways accordingly. Their duty was to hold the gates of heaven, which they opened to send forth the chariot of the sun in the morning, and receive it again in the evening. No classical poet has described them with greater beauty than Shelley, in a celebrated passage of his *Prometheus Unbound.* These goddesses are often depicted as forming the train of Venus. (See Homer, *Hymn. ad Ven.* 145.; Hes., *Erg.* ver. 75., and *Hymn. ad Apoll.* ver. 194.; see also *Gray's Ode on the Spring.*)

HOURS, CANONICAL. The seven hours of prayer, observed, it is said, by the Catholic church since the 5th century; chiefly in monasteries. The number seems before that time to have varied, although some peculiar seasons of the day and night were always set apart for this observance. They became finally fixed at seven by the rule of St. Benedict; a number, perhaps, recommended by the literal acceptation of the words of David (Psalm cxix.), "Seven times a day will I praise thee." These hours are termed, in the language of the Latin church, matins, prima, tertia, nona, vespers, completa or completorium, which last takes place at midnight. At the time of the Reformation the canonical hours were reduced in the Lutheran church to two, morning and evening; the "reformed" church never observed them. (See *Bingham's Ant. Eccl.* 5.; *Riddle's Christian Ant.*; *Ersch and Gruber's Encycl.*, "Horæ.")

HOUSE. (Germ. haus.) A human habitation, or place of abode of a family. Among the eastern nations, and those to the south, houses are flat on the top, with the ascent to the upper story by steps on the outside. As we proceed northward, a declivity of the roof becomes requisite to throw off the rain and snow, which are of greater continuance in higher latitudes. Among the ancient Greeks, Romans, and Jews, the houses usually enclosed a quadrangular area or court, open to the sky. This part of the house was by the Romans called the *impluvium*, or *cavædium*, and was provided with channels to carry off the waters into the sewers. Both the Roman and Greek

house is described by Vitruvius, to whose works we must refer the reader for further information on these heads. The word *house* is a term used in various ways; as in the phrase "a religious house," either the buildings of a monastery, or the community of persons inhabiting them, may be designated. In the middle ages, when a family retired to the lodge connected with the mansion, or to their country-seat, it was called "keeping their secret house." (See *Northumberland Household Book*.) Every graaation of building for habitation, from the cottage to the palace, is embraced by the word house; so that to give a full account of the requisites of each would occupy more space than could be devoted to the subject in this work: indeed to say more would be to write a treatise on domestic architecture.

HOU'SEHOLDER. In Law, the occupier of a house. Where the right of voting for members of parliament is in inhabitant householders, it has been settled by a current of decisions that no one is to be considered as such who does not possess the exclusive right to the use of the outward door of the building. He retains the character, however, although by taking inmates he may for a time have relinquished the exercise of that exclusive right. The "outward door," to satisfy this description, need not be a door opening on the public way; a room or set of rooms having a separate and exclusive outward door (as chambers in one of the Inns of Court) may in the eye of law constitute a house. The same principle is followed in criminal law, where, to constitute the offence of burglary, it is necessary that a "house" shall have been broken and entered.

HOUSEHOLD, THE KING'S. The chief officers of the king's household are,—1. The lord chamberlain; under whom are the vice-chamberlain, groom of the stole, lords of the bedchamber, gentlemen of the privy chamber, &c. 2. The lord steward; in whose office are the treasurer and comptroller of the household, yeomen of the guard, gentlemen pensioners, master of the horse, &c.

HOUSEHOLD TROOPS. *See* GUARDS.

HOUSE OF CORRECTION. A prison for the punishment of idle and disorderly persons, vagrants, trespassers, &c. They are regulated by 4 G. 4. c. 64. and other statutes. *See* BRIDEWELL, PRISON.

HOU'SING. (From house.) In Architecture, the space taken out of one solid to admit of the insertion of another.

HO'VEL. An open shed for sheltering cattle, for protecting produce or materials of different kinds from the weather, or for performing various country operations during heavy rains, falls of snow, or severe frosts.

HOW'ITZER. (Germ. häufen, *to fill up*.) A species of mortar, or piece of ordnance, of iron or brass. The iron howitzers used in the British service are four or five feet long, and eight or ten inches diameter.

HOY. A small vessel having generally one mast.

HUBERT, ORDER OF SAINT. The highest Bavarian order of knighthood, founded in 1444.

HUE AND CRY. In Law, the common process of pursuing a felon. This custom is of ancient origin, and evidently arose from the practice of pursuing the offender with a loud outcry, that all might try to bring him to justice.

HU'GUENOTS. In French History, a name given in the sixteenth century to the Protestants or Calvinists of France. The writers of that time were not acquainted with the true derivation of this popular nickname, to which they assigned various absurd etymologies; it is, undoubtedly, a corruption of the German "Eidgenossen," signifying the Swiss confederates. Geneva was the literary and ecclesiastical metropolis of the French reformed; and consequently they were naturally confounded, in the eye of the Catholic populace, with the Swiss, who supported that republic by their alliance. After a long period, during which they increased in numbers under occasional persecution (under Francis I. and Henry II.) a large party of the Huguenots took part in the conspiracy of Amboise in 1560; and although the free exercise of their religion was secured to them by the edict of January (1562), yet they were driven by the violations of that edict to take up arms against the government of Francis II. in the same year. At that period their leaders were of the houses of Bourbon (King of Navarre and Prince of Condé) and Chatillon (the Admiral Coligny). They were powerful in numbers, and still more in wealth and consequence. A very large proportion of the higher nobility; of the middle nobility and gentry, especially in the central and south-western parts of France; the whole or greater part of the population in some towns, as Rouen, La Rochelle, Dieppe, Nismes; finally, a large body among the peasantry in some districts, especially of the south, where the doctrines of the Albigeois were never fully extinguished; — these belonged to their party. But during the religious wars of the 16th century they gradually lost ground under the increasing zeal and fanaticism of the great Catholic body; and after the conversion of Henry IV. most of their chiefs among the nobility successively abandoned the faith. They sustained two civil wars in the following century against Louis XIII., which cost them the loss of the strong places which they had held, and of many of their privileges. The history of the Protestant church in France then ceased to be the history of a political party; and the name of Huguenots, about the same time, began to pass out of ordinary use. De Thou, Davila, D'Aubigny, Lanoue, are perhaps the most valuable of the numerous cotemporary historians of the 16th century. Of modern compilations, *Smedley's History of the Religious Wars of France;* Wraxall; Sismondi, vols. xvi. to xx.; *Browning's History of the Hugonots from the Edict of Nantes*, an useful compendium, with references to the best authorities, published in 1839.

HUI'SSIER. (Fr. from the old word huis, *a door;* whence our *usher*.) Executive officers in the French courts of justice, whose original function was to keep the door of the tribunal. Such officers were styled by the Romans apparitores, cohortales, executores, and by a variety of other names. In France the huissiers were originally a subdivision of the general class of *servientes, sergens;* but afterwards these latter came to be called indiscriminately huissiers. Their functions are now numerous and important. They give notice on behalf of and execute the processes of the courts to which they are attached, both civil and criminal. Those of the Court of Cassation are appointed by itself; those of the Cours Royales on the recommendation of those courts; those of courts of commerce by the government. The officers termed huissiers-priseurs, or commissaires-priseurs, are employed as appraisers at public sales.

HU'LFSTON. (Germ.) In Music, the secondary or superior note in a shake. *See* HAUPT TON.

HULK. The name given to an old ship laid by as unfit for further service. The hulks near Woolwich consist of old ships to which convicts are sent previously to their departure from the country.

HULL. The body of a ship, exclusive of the masts, rigging, &c.

Hull down, expresses that the hull of the ship is concealed by the convexity of the sea.

HUMANITA'RIAN. A term sometimes applied to those who deny the divinity of Christ, and assert him to have been *mere man*. This, however, is more than the word exactly signifies, and the term Psilanthropist, or mere Humanitarian, has been suggested as conveying the idea more precisely. *See* SOCINIAN, UNITARIAN.

HUMA'NITIES. A word employed in modern European schools and colleges of various nations, to signify grammar, rhetoric, and poetry, including the study of the ancient classics. It has the same sense with polite literature. A student in humanities (literæ humaniores) is termed a *humanist*.

HU'MBLE BEE, *See* MELLIFERA.

HU'MBOLDTINE. A native oxalate of the protoxide of iron. It occurs crystalline and massive, and of a yellow colour; the massive variety is earthy and greenish yellow.

HU'MBOLDTITE. A name given to a variety of *Datholite*, or borosilicate of lime. It occurs crystallized. These minerals are named in honour of Humboldt, the celebrated traveller.

HU'MERUS. (Lat.) The bone of the arm. The first of the radiated system of bones of the anterior extremity, articulated with the scapula in the vertebrated animals. In Entomology, Mr. Kirby so calls the third joint of the anterior pair of legs in Hexapod insects.

HU'MIFU'SUS (Lat. humus, *the ground*, and fundo, *I pour or spread out*), in Botany, denotes the spreading of plants over the surface of the ground: procumbent.

HUMIRIA'CEÆ. (Humirium, one of the genera.) A natural order of arborescent or shrubby Exogens, inhabiting Brazil, but not very well understood. They differ from *Meliaceæ* in their albuminous seeds and their slender embryo; agreeing in the latter respect, and in their balsamic wood, with *Styraceæ*. *Humirium floribundum* yields, on being wounded, a liquid yellow balsam, called Balsam of Umiri, resembling the properties of Copaiva and Balsam of Tolu.

HU'MITE. A mineral named in honour of Sir Abraham Hume, in whose celebrated collection it was found. It occurs in yellow-brown or colourless crystals on Monte Somma. It has not been analyzed.

HU'MMING BIRD. *See* TROCHILUS.

HUMOUR. *See* WIT.

HU'MOURS OF THE EYE. *See* EYE.

HU'NDRED. A hundred is a territorial division, having for its object the more convenient and efficient administration of justice; anciently subsisting in other countries, particularly France and Lombardy, as well as in England, and adopted in this country as the subdivision of a county. The institution of the hundred, as well as that of the county and tything, is, upon no precise authority, usually referred to the reign of Alfred; but it is probable that the division was of an older date, and that it was not introduced into all parts of England at the

same time. It is certain, at any rate, that the term had not in all parts the same application; for the meaning usually given to it, namely, that of a district containing a hundred free families, even if it be reconcilable with what appears to have been in early times the state of the population in the southern counties, is totally inconsistent with any reasonable conjecture as to the population of the north, where the hundred generally includes a much larger district. It is probable, therefore, that the term having originated in the south with the meaning stated, was subsequently applied to the divisions previously established in the northern counties under the name of Wapentakes. To each hundred belonged a court baron, similar in the nature and extent of its jurisdiction to the county court, and also a court leet (*see* tit. LEET); both of which were usually, and by the common law, held either by the sheriff, or by a deputy or steward having authority under him. But in some cases the jurisdiction of the court baron and court leet, or of one of them, within the hundred, was by special grant of the crown vested in private persons, and exercised by them or their deputies. The essential use of the hundred was in the liability of the hundreders, when offences were committed within their district, either to produce the offender, or make good the damage. This liability, much restricted by statute, still subsists in certain cases of riotous and wilful mischief. The division into hundreds is frequently used in acts of parliament as a convenient mode of reference.

HU'NDRED WEIGHT. A denomination of weight containing 112 pounds. It is subdivided into 4 quarters, each containing 28 pounds. *See* WEIGHTS.

HU'NTERS, *Venantes*. A tribe of spiders are so called which are incessantly running or leaping about in the vicinity of their abode, to chase and seize their prey.

HU'RDLE. A frame usually made of wood, but sometimes of iron, for the purpose of forming temporary fences. The frame consists of two perpendicular stakes, into which are fixed five or six horizontal bars, and the whole is braced together by one or two diagonal pieces. When a fence is to be formed the hurdles are put down end to end; and they are made fast to the ground by the insertion of the lower end of the stakes into it, and to one another by a tie fastened round their upper ends, or by a moveable wooden pin passed through them.

HURO'NIA. A name given by Mr. Charles Stokes to certain radiated articulated bodies formerly referred to the *Polyparia*, found in the transition limestone of Lake Huron. (*Geol. Trans.* vol. i., New Series.)

HU'RRICANE. (Span. huracan.) A violent storm, generally accompanied by thunder and lightning, and distinguished from every other kind of tempest by the vehemence of the wind, and the sudden changes to which it is subject. Hurricanes prevail chiefly in the East and West Indies, the Isle of France, and in some parts of China. The following graphic description of the usual phenomena attending the West Indian hurricanes, from the pen of Edmund Burke, may be interesting to the reader: — "It is in the rainy season, principally in the month of August, more rarely in July and September, that they are assaulted by hurricanes, the most terrible calamity to which they are subject from the climate. This destroys at one stroke the labour of many years, and frustrates the most exalted hopes of the planter, and often just at the moment when he thinks himself out of the reach of fortune. It is a sudden and violent storm of wind, rain, thunder, and lightning, attended with a furious swelling of the sea, and sometimes with an earthquake; in short, with every circumstance which the elements can assemble that is terrible and destructive. First they see, as a prelude to the ensuing havoc, whole fields of sugar-canes whirled into the air, and scattered over the face of the country. The strongest trees of the forest are torn up by the roots and driven about like stubble. Their windmills are swept away in a moment. Their works, their fixtures, the ponderous copper-boilers and stills of several hundred weight, are wrenched from the ground and battered to pieces. Their houses are no protection; the roofs are torn off at one blast, whilst the rain, which in an hour rises five feet, rushes in upon them with an irresistible violence. There are signs which the Indians of these islands taught our planters, by which they can prognosticate the approach of a hurricane. It comes on either in the quarters or at the full or change of the moon. If it will come on at the full moon, you being at the change, observe these signs. That day you will see the sky very turbulent. You will observe the sun more red than at other times. You will perceive a dead calm, and the hills clear of all those clouds and mists which usually hover about them. In the clefts of the earth, and in the wells, you will hear a hollow rumbling sound like the rushing of a great wind. At night the stars seem much larger than usual, and surrounded with a sort of burs. The north-west sky has a black and menacing look, and the sea emits a strong smell and rises into vast waves, often without any wind. The wind itself now forsakes its usual steady easterly stream, and shifts about to the west, from whence it sometimes blows with intermissions violently and irregularly for about two hours at a time. You have the same signs at the full of the moon. The moon itself is surrounded with a great bur, and sometimes the sun has the same appearance." *See* STORMS, TORNADO.

HURST. (Sax.) A wood; hence the termination of the names of several places in England, particularly in Kent and Sussex.

HU'SBANDRY. A comparatively primitive term, including both agriculture and gardening, or all those country occupations which the father of a family is expected to perform in the country. The term is very commonly used as synonymous with agriculture. The Berwickshire husbandry, the convertible husbandry, are terms used in agriculture for certain systems of cropping in which the land is alternately kept under grass and tillage.

HUSSA'RS. A name given to some well-known equestrian troops, used in all the armies of Europe. The term is of Hungarian origin (being derived from husz, *twenty*, and ar, *pay*, every *twenty* houses furnishing *one* man), and was first applied to the body of troops raised by the nobles of Hungary on occasion of the appeal made to the latter in 1458 by Mathias Corvin. The equipments of such troops are extremely light and elegant, and their arms consist of a sabre, a carbine, and a pair of pistols. In the British cavalry there are five regiments of Hussars.

HU'SSITES. The followers of John Huss, a Bohemian reformer and divine, who was convicted of heresy by the council of Constance, and burnt by order of the Emperor of Germany, in 1415. The circumstances attending the origin of this sect are interesting; inasmuch as while, on the one hand, there is no doubt but that the writings of Huss and Jerome of Prague were the source from which Luther drew a great part of his opinions and views, it is ascertained at the same time that it was from the books of Wiclif that Huss was himself induced to institute his bold inquiries into the faith and morals of the church. The errors which were charged against him contain many of the opinions now held by all Protestants; but several of these he himself denied, and those for the assertion of which he ultimately suffered have neither been universally held by reformers, nor seem of very great importance. They were these: — 1. That Pope Sylvester and the Emperor Constantine did evil to the church when they enriched it. 2. That if any ecclesiastic be in a state of mortal sin, he is disqualified for the administration of the sacraments. 3. That tithes are not dues, but merely eleemosynary. On the other hand, he held the Romish idea of transubstantiation; and the opinion of the necessity of communion in both kinds, which became afterwards the most remarkable feature in the doctrines of the Hussites, is not in reality to be ascribed to their founder. The condemnation of Huss is also remarkable, as it is from the circumstances attendant on it that the imputation of not keeping faith with heretics is originally charged upon the Roman church. The Emperor Sigismund gave Huss a safe conduct, to secure him from any ill consequences that he might apprehend from delivering himself up voluntarily to be examined by the council. Nor did the council assert any right to condemn him. They handed him over to the secular arm, to the emperor himself. But it is confidently asserted that when the emperor scrupled to violate a promise which was undoubtedly binding upon him, it was at the pressing instance of the pope or cardinals that he allowed the execution to take place. The apologists of the Roman Catholics in this matter affirm that this safe conduct imported only that Huss might *go to Constance* without being harmed; the words of the original instrument, however, are reported to be, "Transire, stare, morari, redire liberé permittatis."

After the execution of Huss, and of his disciple Jerome in the following year, there arose a violent insurrection among their partizans in Bohemia, who maintained themselves for many years by force of arms, and split into two sects, under the denominations of the Calixtines and the Thaborites. The former, so called from demanding the cup in the sacrament, were finally reconciled to the church by the concession which they required. The latter were so called from the name they gave to the hill on which they pitched their camp in the neighbourhood of Prague, and carried their notions upon the authority of the church and its ministers, ceremonies, and all the exterior of religion, to the length of an extravagant simplicity. The Bohemian Brothers and the Beghards, who gave so great an impulse to the Reformation, were the descendants of this branch of the Hussites. (Cochlæus, *Historia Hussitarum*; *Gieseler's Text-book*, iii. 355., translation.)

HU'STINGS. (Either from the French hausser, *to lift*, or Sax. hus, *house*, and ting, *court* or *judgment*.) The principal court of the city of London, held before the lord mayor and aldermen: also, in common language, the booth or elevated place on which candidates at a parliamentary election are proposed, and address their constituents.

HUTCHINSO'NIANS. The name given to those who embraced the opinions of John Hutchinson, a well-known philosopher and naturalist of the 18th century. Though the followers of Hutchinson have never constituted a sect, they have reckoned among their number several distinguished divines both of the established churches of the United Kingdom and of dissenting communities. The number of professed Hutchinsonians is rapidly decreasing, though the principles and views of their founder are still entertained by many. The chief characteristics of Hutchinson's philosophy consist in his rejection of Newton's doctrine of gravitation; and in his maintaining the existence of a plenum on the authority of the Old Testament, which according to him embraces a complete system of natural philosophy as well as of religion. See his works, 12 vols. 8vo. 1748.

HY'ACINTH. (Gr.) In Mineralogy, one of the names given to the yellow or brown crystals of zircon. It occurs in beds of streams and rivers, especially in Ceylon, along with rubies, sapphires, &c. Its most usual form, when in crystals, is a four-sided prism terminated by four rhombic planes.

HYACI'NTHUS. In Grecian Mythology, the son of Amyclas king of Laconia, and of the muse Clio, accidentally killed by Apollo while they were playing at quoits. The story is thus related:—Zephyr, enraged at the preference displayed by Hyacinthus for Apollo, caused the wind of which he was the god to turn from its course a quoit thrown by Apollo, which hitting him on the forehead instantaneously caused his death. The latter immortalized his favourite by causing the flower which still bears his name to spring from his blood, and inscribing the word AI (Gr. αι, *alas*) on its leaves, to indicate the deep grief of the god for his loss. An annual festival named Hyacinthia, was celebrated at Amyclæ in honour of Hyacinthus. (*Athen. Deipn.* iv. p. 139.)

HYACY'NTHINE. A brown or greenish mineral in eight-sided prisms, transparent and doubly refractive.

HY'ADES. (Gr. ὕειν, *to rain.*) In Mythology, the name given to the daughters of Atlas and Pleione, who, overwhelmed with grief at the fate of their brother Hyas, who was torn in pieces by a bull, are said to have wept so violently that the gods, in compassion, took them into heaven and placed them in the Bull's forehead, where they still continue to weep, and are thence supposed to presage rain. They form a cluster of five stars in the face of Taurus.

HYADES. *See* TAURUS.

HYÆ'NA. (Gr. Ὑαίνα.) A genus of digitigrade Carnivorous Mammals, separated by Storr from the *Canis* of Linnæus, from which it not only differs in dentition and other important particulars, but, in general, manifests a closer affinity with the *Viverridæ;* between which and *Felis*, the genus *Hyæna* is placed by Cuvier. The characters of this genus are, five molars above and four below, on each side, the three anterior molars being conical, smooth, and remarkably large, adapted for breaking the bones of their prey; the tongue has a broad patch of cuticular spines on the anterior part of its dorsum; the legs are each terminated by four claws; there is a peculiarly large perineal glandular pouch; and the neck and jaws are remarkable for the strength of their muscles. The species of hyæna are nocturnal; they prey on dead carcasses. An extinct species (*Hyæna spelæa*) was abundant in England and France anterior to the glacier epoch, and has left its remains in many caverns in both countries.

HYALÆ'A. (Gr. ὕαλος, *glass.*) A genus of beautiful Pteropodous Mollusks, remarkable for the delicacy and transparency of the shell. This bears a close resemblance to a bivalve, with the two valves unequal and soldered together at the hinge. That portion of the shell which corresponds to the ventral aspect of the animal is convex; the dorsal plate is nearly flat, and is longer than the other; the hinder or closed margin of the shell is produced into three sharp points. The inhabitant is provided with two large wing-like processes of the mantle, which it protrudes, when swimming, from the anterior open fissure of the shell. The species are found floating in the Mediterranean and tropical seas.

HY'ALITE. (Gr. ὕαλος, λιθος, *a stone.*) A yellow or grey variety of uncleavable quartz or opal; it is commonly concretionary or chalcedonic, of a vitreous fracture and lustre. It occurs in trap rocks in grains, filaments, and rhomboidal masses: it is silica combined with about 6 per cent. of water.

HY'ALOID. (Gr. ὕαλος, and εἶδος, *form.*) A term applied to transparent membranes, and more particularly to that which invests the vitreous humour of the eye.

HYBERBO'REANS. (Gr. ὑπερ, *beyond*, and βορειας, *the north wind.*) The name given by the ancients to the unknown inhabitants of the most northern regions of the globe, who, as their name implied, were supposed to be placed beyond the influence of the north wind, and consequently to enjoy a mild and delightful climate. The question of the existence and exact situation of the Hyberboreans long formed one of the most intricate in the whole compass of ancient history; but the general opinion now inclines to regard them as synonymous with the Laplanders, Norwegians, and some other nations of northern Europe. (See the *Encyc. des Gens du Monde.*)

HYBERNA'CULUM. A term invented by Linnæus to denote a leaf-bud; which he rightly considered the winter-quarters of the point of growth in a plant.

HY'BERNATION. (Lat. hybernus, *wintry.*) The act by, or the state in, which certain animals exist during that season of the year when excess of cold or of heat, or lack of food, prevents their going abroad and performing their customary functions. As the state is generally superinduced by the rigours of winter, it has received its denomination from that circumstance; but in the tropics the effects of the hottest and driest weather, in reducing the numbers of the insect world, are such as to render it necessary for many reptiles and some insectivorous mammals, as the *Tenrecs*, to pass into a state of inactivity or torpidity, in order to maintain life until the recommencement of the rainy season. The condition of hybernation is, in fact, less the alteration of temperature, than the abstraction of the means of subsistence dependent thereon; as, *e.g.*, the disappearance of insects in the winter season of our own climate.

Animals so highly organized as the warm-blooded and quick-breathing mammalia cannot maintain their complicated organic machinery in action without frequent supplies of food: an interruption in this respect of a few days, or at most a few weeks, is fatal. If, therefore, the phenomenon of hybernation had been known only in the cold-blooded classes, an insectivorous mammal in a climate where insects could not subsist for several months in the year would be inconceivable. The modification of the vital powers by which a warm-blooded animal is made even temporarily to assume the state and properties of a reptile, is perhaps one of the most striking instances of special adaptations to meet an exceptional case that the history of animals presents. When the atmosphere becomes vacant of insect life, and the bat, in its nocturnal flittings, would vainly traverse it in search of food; and when the few insects that survive the winter have burrowed too deeply in the earth, or concealed themselves in hiding-places too secure for the reach of the hedgehog,—these species, with starvation staring them in the face, are preserved by the suspension of those functions, the maintaining of which in a state of activity is essentially dependent on an uninterrupted supply of nutriment. The bat suspends itself in the innermost recesses of its cave, the hedgehog creeps to its concealed nest, and both resign themselves to deep repose; but the breathing becomes gradually slower than in ordinary sleep, the pulsations of the heart diminish in force and frequency, the supply of stimulating arterial blood to the muscles and the brain is progressively reduced, relaxation of the muscular fibres is converted into stiff inaction, and sleep sinks into stupor: at length respiration entirely ceases, and with it those chemical changes in the capillary circulation on which animal heat mainly depends. The preservation of life, in its passive or latent state, is now due to the irritable property of the heart's fibre, which is excited to contract by the blood in its present dark or carbonized state, and continues to propel it slowly over the torpid frame during the whole period of hybernation. This slow circulation of venous blood through both the pulmonic and systemic vessels is the only recognizable vital act during that period, and the material conveyed by the absorbents into the circulating fluid is sufficient to counterbalance the slight waste thus occasioned. So long, therefore, as the state of torpidity continues, the hedgehog and bat are independent of supplies from without, but they purchase that independence by a temporary abrogation of their vital faculties: cold, senseless, motionless, and asphyxiated, their entry into death's chamber is prevented only by their being brought to his very door.

The hybernation of lizards, snakes, frogs, toads, and other cold-blooded reptiles, is accompanied by analogous changes, differing only in degree; for as the heart in these animals is, at all times, destined to propel blood imperfectly oxygenated,—as the respiratory or oxygenating apparatus is imperfect,—and as the heat of the body in them rises and falls with the external temperature, a slight deterioration of these lower conditions of the circulating and respiratory functions induces torpidity, with the consequent loss of appetite and independence of food. Some quadrupeds, as the dormouse and squirrel, which subsist on articles of diet better adapted to be laid up in store than insects, carry a winter provision to their hybernating nests; and their torpidity is more nearly allied to a profound but ordinary sleep; respiration is never wholly suspended; the waste of the organism is proportionate to the degree of activity in the working of the machine, and they occasionally rouse themselves and take in the requisite supply from their provident store. Insectivorous birds, being independent, through their power of traversing space, of the vicissitudes of climate

and their consequences, transport themselves, when their food fails in one country, to latitudes favourable to its abundance: hence the immigration of the cuckoo and swallow at the commencement of the genial season, and their subsequent disappearance.

HY'BRID. (Gr. ὕβρις, *a mule.*) The produce of a female plant or animal which has been impregnated by a male of a different variety, species, or genus.

The most common hybrids are those which result from the connection of different varieties of the same species, as the produce of the wild boar and domestic sow; the endless modifications which result from analogous interbreeding from varieties of the rose and other ornamental or useful plants are familiar examples of the principle among vegetables.

Specifical hybrids have been produced from the artificial fertilization by Kœlreuter of the *Nicotiana rustica* with the pollen of the *Nicotiana parriculata;* and Schiek has demonstrated, by numerous observations, that a multitude of plants produce specifical hybrids in a state of nature.

Hybrids from different species of insects, under similar circumstances, have been obtained; as from the connection of *Papilio jurtina* with *P. janira*, of *Chrysomela œnea* with *Chr. alni*, of *Phalangium cornutum* with *Ph. opilio*. Specifical hybrids have been obtained in the class of fishes by artificial impregnation between the *Cyprinus carpio* and *Cypr. carassias*, and between the *Cypr. carpio* and *Cypr. gibelio*. In birds, hybrids have been bred between the goldfinch and canary, between the reeves and the common pheasant—the pheasant and the common fowl—the swan (*Anas olor*, L.) and the goose (*Anas anser*, L.*)—between the *Tetrao tetrix* and *Tetrao urogallus*—between the *Corvus corone* and *Corvus cornix*, &c. Among Mammals, hybrids have been produced between the lion and tiger, the dog and wolf, the dog and jackal, the dog and fox, the goat and ibex, the horse and zebra, the zebra and ass, and the horse and ass; the produce of the two last species, as it is the most common and useful of hybrids, being termed *par excellence* "the mule."

But a fruitful connection is not only possible between individuals of different varieties or of distinct species, but also occasionally between animals of different genera. Generical hybrids have thus resulted from the union of the goat (*Capra hircus*) with the antelope (*Antilope rupricapra*), of the stag with the cow, and of the bull with the sheep, notwithstanding their disparity of size. Among reptiles, between the toad (*Bufo*) and the frog (*Rana*); among insects, between *Cantharis melanura* and *Elater niger*, and between *Melolontha agricola* and *Cetonia hirta*. Experiment alone can determine the amount of affinity beyond which fertilization is impracticable, but at present it seems to be restricted to individuals belonging to genera of the same natural group.

The tendency of all the natural phenomena relating to hybridity is to prevent its taking place, and when it has occurred to arrest the propagation of varieties so produced, and to limit their generative powers so as to admit only of reversion to the original specific forms.

It would seem that in most cases the fertilizing particles had a specific power over the ova derived from the same species, or were attracted by them in a peculiar manner; for the milt and roe of different species of fishes are not unfrequently excluded in the same locality, yet hybrids are not met with in consequence. Spallanzani was not able to impregnate the ova of the frog with the semen of the newt, nor to produce a fertile combination of those of the toad and newt; nor did the injection of the semen of the dog into the vagina of the cat impregnate any of her ova.

The individuals of different species which produce a hybrid offspring do not voluntarily copulate. The salacious mare must be blindfolded, or she will not receive the ass. The stallion refuses to mount the she-ass, if a mare be in sight. Hunter states that, being desirous "to have a she-wolf lined by some dog, she would not allow any dog to come near her, but was held while a greyhound dog lined her; while in conjunction she remained pretty quiet, but when at liberty endeavoured to fly at the dog." Buffon reared puppies of the wolf, fox, and dog together, to familiarize them with each other; but when they were in heat, the females of each species exhibited an insurmountable repugnance to the male of the others, and mortal combats ensued instead of fertile union between the different sexes of the different species. (*Annales du Muséum*, t. xii. p. 119.)

In a few exceptional cases, serving only to establish the rule of their infertility, specifical hybrids have been known to propagate together, and produce a degenerate intermediate race, which soon becomes extinct: it more commonly happens that a hybrid is sterile, or propagates only with an individual of pure breed.

On the assumption that a hybrid produced by two individuals of undoubtedly distinct species is sterile, experiments have been made on the breeding powers of hybrids, to determine the nature of doubtful species. Thus Hunter believed that he had obtained absolute proof of the jackal being a dog, and to have equally made out the wolf to be of the same species; and he then proceeds to speculate whether the wolf is from the jackal, or the jackal from the wolf; for he had obtained pups from the connection of a female hybrid jackal-dog and a male terrier, and between a female hybrid dog-wolf and a male greyhound; and he adds, in respect of the latter fact, that "it would have equally proved the same fact if she had been lined either by a wolf, a dog, or one of the males of her own litter." (*Hunter's Animal Œconomy*, by Owen, 8vo. p. 323.) But this assertion, that the fertility of a hybrid with an individual of a pure breed proves the fact of the identity of two supposed distinct species equally with the production of offspring from the connection of hybrid with hybrid, cannot be admitted. To prove the identity of two supposed distinct species, on the assumption that the fertility of the hybrids from the two gives the proof required, it should be shown that such hybrids are fertile among themselves, and capable of propagating indefinitely an intermediate variety. Hunter's celebrated experiments, however, only proved that two nearly allied species will produce a hybrid offspring, and that such hybrid may be impregnated by an individual of the pure breed; but this fact illustrates the general law by which the reversion of the hybrid to the pure breed is provided for; while, on the other hand, the intermixture of distinct species is guarded against by the aversion of two specifically different individuals to sexual union.

HYDA'RTHRUS. (Gr. ὕδωρ, and ἄρθρον, *a joint.*) The white swelling: the joints most subject to it are the knee, elbow, wrist, and ankle. It is distinguished from rheumatic swelling of the joints by a fixed and wearing pain preceding the tumefaction, and often existing for a long time before any enlargement of the part is perceptible; also by the general state of the habit.

HYDA'TIDS, *Hydatis.* (Gr. ὑδατίς, *a bladder.*) A term somewhat vaguely applied both to morbid cysts and true Entozoons of the order *Cystica*. Of the latter some are globular, with a tunic composed of a double albuminous membrane between which the sporules or ova are developed. In the species developed in the human liver, the ova are detached from the internal surface, and it is hence termed *Acephalo-cystis endogena*. In a species infesting similar organs in the lower animals the ova are detached from the external surface, and it is called *Acephalo-cystis exogena*. In a higher organized genus of Hydatids, a slender more or less elongate process is continued from the cyst, and terminates in an extremity provided with suckers and a coronet of recurved hooklets, like the head of a tape-worm: this genus is termed *Cysticercus*. Another genus has numerous similarly organized appendages attached to the cyst, and is accordingly termed *Cœnurus*. It is an hydatid of the last genus which is developed in the brain of sheep, and produces the "giddy sickness" or "staggers."

HYDE, or HIDE. A measure of land, common in Domesday Book and old English charters. Its derivation is obscure. It is somewhat fancifully drawn from the ancient fable (common to many nations) of the deceit practised by a colonist in acquiring from the owners so much land as he could cover with the hide of an ox, and then dividing it into strips so as to make it extend over a large space. Its contents are also uncertain, but are stated by some authorities to amount to 100 Norman or 120 English acres. (*Warner's Hist. of Hampshire; Ellis's Introduction to Domesday.*)

HY'DRA. In Mythology, a fabulous many-headed monster, which was said to infest the lake Lerna in Peloponnesus. According to the fable, on one of its heads being cut off it was immediately succeeded by another, unless the wound was cauterized. It was one of the labours of Hercules to destroy this monster, which he is said to have accomplished by the constant application of firebrands to the wounds as the heads were cut off. The term *hydra* is sometimes used in a metaphorical sense for any manifold evil.

HY'DRA. This once dreaded name is restricted in modern Zoology to a genus of minute fresh-water Polyps. The term *Hydrus* was applied by Linnæus to a genus of water-snakes.

HY'DRA. One of the ancient constellations in the southern hemisphere.

HYDRA'CIDS. Acids containing hydrogen as one of their essential elements; such as the hydrochloric or muriatic acid, the hydriodic acid, &c.

HY'DRAGOGUE. (Gr. ὕδωρ, *water*, and ἄγω, *I expel.*) The term is generally applied to violent cathartics, which bring away a large quantity of watery secretion from the intestines.

HYDRA'RGO-CHLORIDES. Compounds of the bichloride of mercury with other chlorides, forming a class of haloid salts.

HYDRARGY'LLITE. (Gr. ὕδωρ, Lat. argilla, *clay.*) A name given to the native phosphate of alumina, under

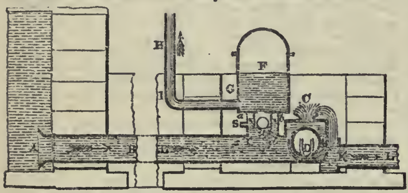
the erroneous idea that it consisted of alumina and water.

HYDRARGY'RIA. (Gr. ὑδωρ, and αργυρος, *silver.*) An eruptive disorder occasioned by the use of mercury.

HYDRA'RGYRUM. Quicksilver, or mercury.

HY'DRATES. Compounds containing water as one of their proximate elements, and in definite proportion. Caustic potash is a *hydrate of potassa*, composed of 1 equivalent of potassa = 48, and 1 of water = 9. Slaked lime, which is an apparently dry white powder, is a *hydrate of lime.*

HYDRA'ULIC RAM, or WATER RAM. An ingenious hydraulic machine for raising water by means of its own impulse. The principle of its action and the mechanism of its construction may be described as follows:—



The water arriving at A from the reservoir with the velocity due to the height of the fall passes along the pipe A B, which should have an inclination of at least an inch for every two yards, escapes through an orifice C, which may be shut at pleasure by means of a valve. A reservoir, F, filled with air is attached by means of a cylinder, *a b c d*, to the pipe A B D; in the middle of the bottom of the reservoir F is a circular orifice, to which there is adapted a short cylindrical tube, of which the extremity E is also furnished with a valve. Another valve S serves to supply the air to the space comprised between the cylinder *a b c d* and the tube E. G I H is an ascensional tube rising from the reservoir F. The water which escapes at C is carried off by the waste pipe K L.

The form of this apparatus (or perhaps its mode of action) suggested the name it has received. The pipe A B C is called the *body of the ram;* and the extremity, where the valves and the reservoir F are placed, is called its *head.* Both valves D and E are formed of hollow balls supported on muzzles, and of such a thickness of metal that they weigh about twice as much as the quantity of water they displace.

We may now consider the effects of the engine when in action. The water flowing through the orifice C acquires the velocity due to the height of the fall, and raises the ball D from its support till it comes to the orifice C; the extremity of this orifice is covered with leather, or with cloth filled with pitch, so that when the ball is applied to it the passage of the water is effectually prevented. As soon as this orifice is closed, the water raises the ball E which had shut the orifice of the reservoir F; and a portion of it introduces itself into this reservoir, and into the pipe G I H. It thus loses the velocity which it had when the orifice C was shut, and the balls D and E fall down in consequence, the one on its support, and the other on the orifice at E. When this takes place, every thing is in the same state in which it was at first. The water begins again to flow through the orifice C; the valve D is again shut; and the same effects are repeated in an interval of time, which, for the same ram, undergoes little variation.

Every time the impulse is renewed a quantity of water is forced up into the reservoir F and the tube H; and as it is prevented from returning by the action of the valve, it must necessarily be delivered at the extremity of H. The use of the air-vessel F is to keep up a continuous motion of the ascending column of water. The communication with the external atmosphere being cut off, the air within F is compressed by a force proportional to the height of the surface of the water in H above its surface in F; and this compressed air acting by its elasticity on the water, maintains a continuous flow through H. The air-vessel, however, though it assists the action of the ram is not an essential part of it; the continuity of the discharge of water may be effected by means of two or more rams, of which the ascensional pipes G I H all terminate in a single branch. On this principle works have been erected at Marly, in France, which raise water in a continuous jet to the height of 57 *mètres*, or 187 English feet.

As the ascending column of water communicates with the air in the reservoir F, this would soon be exhausted if a fresh portion of air were not introduced at each stroke of the ram. The little tube S, which is stopt by a valve opening inwards, serves for this purpose. At the instant when the orifice C is closed a recoil takes place, by which the water is thrown back from the head of the ram towards the cistern; and a partial vacuum being thus produced within the cylinder *a b c d*, the pressure of the external atmosphere forces open the valve in the canal S, and a portion of air enters the cylinder, whence it is driven into the reservoir, excepting the small part of it which lodges in the space between the cylinder *a b c d* and the tube E. (Hachette, *Traité des Machines.*)

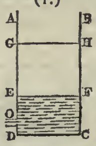
The invention of the hydraulic ram, at least in the improved form here described, belongs to Montgolfier of Montpelier. A machine, however, on the same principle had previously been suggested, and even erected at Chester, by our countryman Mr. Whitehurst, but much less perfect in its mode of action; for the orifice C, instead of being opened and shut by the action of the water itself, required to be opened and shut by the hand by means of a stop cock. Owing to this circumstance, Whitehurst's machine was of little utility, and appears to have soon been entirely forgotten.

HYDRAU'LICS (Gr. ὑδωρ, and αυλος, *a pipe*), is that branch of natural philosophy which treats of the motions of liquids, the laws by which they are regulated, and the effects which they produce. By some authors the term *Hydrodynamics* is usually applied to the general science of the motions of fluids; while *Hydraulics* is more particularly applied to the art of conducting, raising, and confining water, and to the construction and performance of water-works.

There is no part of mechanical science which offers greater difficulties to the mathematician, or where the results of theoretical investigation present so little agreement with experience. This arises from the excessively complicated nature of the movements which take place among the particles of a liquid mass when its equilibrium has been disturbed, and partly from the great number of disturbing causes by which those movements are affected.

The first and principal problem of hydraulics is to determine the velocity with which a liquid flows through an aperture in the bottom or sides of the containing vessel.

(1.)



In order to discover the law of this velocity, let A B C D (fig. 1.) be a vessel filled with water to the height E F, and let O be a very small opening in the side of the vessel; while the water stands at E F it will issue from O with a certain velocity depending on the height E F above O. Let it therefore be proposed to determine to what height, G H, the vessel must be filled in order that the velocity of the efflux through O may be doubled. From the principles of hydrostatics it is shown that the force urging a particle of the liquid at O through the orifice is the pressure due to the height of the vertical column above O. Now we may consider, in the first place, that when the velocity of a particle in motion is doubled, the momentum, or moving force, must also be doubled; and, in the second place, that if the velocity of the efflux is doubled, twice the number of particles will be put in motion in the same interval of time; and consequently the momentum or moving force must be doubled on this account also. Hence when the velocity of the discharge through O is doubled, the moving force, which in the present case is the pressure, must be quadrupled. But the pressure is proportional to the height of the fluid above O, hence the height must be quadrupled. By the same process of reasoning we conclude that to obtain a threefold velocity a ninefold depth would be necessary, and so on; and, generally, that the depths must be increased as rapidly as the squares of the velocities; or, in other words, the velocities are proportional to the square roots of the depths of the orifice below the surface.

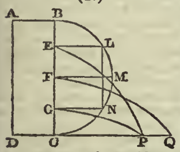
By means of this law the absolute velocity with which water issues from an orifice at any depth under the surface may be ascertained, provided we can determine the velocity for any particular depth. Now if we suppose the orifice O to be on a level with the surface of the liquid, or if we suppose O to be in the bottom of the vessel covered with an infinitely thin film, there would be no pressure on a particle at O, which, therefore, would drop out merely by the effect of its own weight, and consequently with the velocity of a heavy body beginning to fall. But the velocity of a falling body is proportional to the square root of the height from which it has fallen; therefore, since it has been shown that the velocity of the discharge through an orifice is also proportional to the square root of the height of the liquid above the orifice, and that the two velocities are the same in one particular case, it follows that they must be the same in all cases; and hence we have this important theorem:—"The velocity with which a liquid issues from an infinitely small orifice in the bottom or side of a vessel that is kept full, is equal to that which a heavy body would acquire by falling from the level of the surface to the level of the orifice."

Several consequences follow immediately from this fundamental theorem. In the first place, if the aperture is enlarged, each particle of the liquid presenting itself there will escape with the same celerity; and hence the quantity of water that issues through an orifice is as the area or section of the orifice multiplied into the square root of the depth. Again, if the water is thrown up in a perpen-

dicular jet, it ought to ascend to the height of the reservoir; or if several orifices are made in the same vessel, each presented upwards, the jets escaping from each of them would all rise to the same height. But by reason of the resistance of the air, the friction on the sides of the orifice, the mutual cohesion of the liquid particles which impedes their separation and escape, and the action of opposing currents formed in the interior of the liquid, these conclusions must be received with considerable modifications. The effects of the disturbing causes can only be determined by a comparison with experiment.

Water issuing through a hole or pipe in the side of a vessel kept full, like all other projectiles when the resistance of the air is supposed to be withdrawn, describes a parabola in a vertical plane. Let A B C D (fig.2.) be a cylindrical vessel filled with water, and E an orifice in its side; the water will be projected from E with a velocity which would carry it horizontally through double the space B E in the same time that a body falls from B to E. But from the instant it escapes at E it begins to descend with an accelerated motion to the level of D C, while it continues its uniform horizontal flight, and thus describes a parabola meeting the ground in P. Now, by the theory of projectiles, the velocity of a body moving in a parabola is equal to that which is acquired by a body falling through half the parameter of the diameter, and it was shown that the velocity at E is equal to 2 B E; therefore the directrix passes through B, and consequently $4\,BE \times EC = CP^2$. On B C, as a diameter, let there be described a semicircle B L C; then $BE \times EC = EL^2$, and consequently $CP^2 = 4\,EL^2$; whence $CP = 2\,EL$, or the horizontal range is double the ordinate E L. The horizontal range is therefore greatest when the aperture is at F, the middle of B C, and is then C Q, which is equal to 2 F M, or to the altitude B C. In all other cases there are two apertures, E and G, equidistant from F, which give the same range; for by the nature of the circle there are two equal ordinates, E L and G N.

(2.)



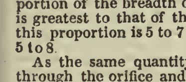
There is a circumstance connected with the efflux of a liquid through an orifice which requires particular attention. While a liquid is flowing out in this manner, the particles continue to descend in vertical lines till they reach within a short distance of the orifice, as at C D (fig.3.), when those not immediately above it change the direction of their motion, and approach the orifice with different degrees of obliquity, converging as it were to a centre, the position of which is somewhat without the orifice. In consequence of this the vein of water as it issues out is contracted, its breadth at *m n* being less than the width of the orifice. This contraction of the jet was first noticed by Sir Isaac Newton, who gave it the name of the *vena contracta*, or the *contracted vein* of the liquid. The distance from the orifice at which the contraction is greatest depends in some degree on the magnitude of the orifice, and is equal to about half its diameter when the orifice is circular and small. The consequence of this contraction is that the discharge of water is not so great as the theory gives it, but is reduced in the proportion of the breadth of the vein where the contraction is greatest to that of the orifice. According to Newton this proportion is 5 to 7 nearly; and according to Bossut 5 to 8.

(3.)

As the same quantity of liquid must evidently pass through the orifice and the contracted vein in the same interval of time, it follows that the velocity at the latter point must be greater; and therefore in applying the theorem respecting the velocity of discharge, it is the velocity at the contracted vein which must be regarded.

It is found by experience that if a short tube, about one or two inches long, is inserted in the vessel, and the water be allowed to flow through the tube, the contraction of the vein is very considerably diminished, and the quantity of water discharged through the tube is considerably greater in the same time than through an orifice of equal diameter. Venturi found that the discharge through a smooth hole in the bottom of a reservoir of tin amounted to 64 quarts in 100 seconds; a short pipe of the same diameter being applied to the bottom of the reservoir, so as to be flat and even with it, the discharge was augmented to 82 quarts in the same time; and on giving the bottom of the vessel the form here represented, leaving the area of the orifice at A (fig.4.) the same as before, the discharge was increased to 98 quarts. By enlarging the lower end of the pipe, and giving it a curvature as B, the quantity of water delivered in the same time received a still farther augmentation. Such additional pipes are called *adjutages*.

(4.)



The velocity and other circumstances relative to the motion of water in conduit pipes, and in open canals and rivers, cannot be accurately determined from any theoretical principles; but very numerous experiments have been made on the subject, from which results have been deduced of great value in directing the practice of the engineer. When water flows from a reservoir in long horizontal pipes of the same diameter, the discharges made in equal times are nearly in the inverse ratio of the square roots of the lengths. But this rule applies only within limits which are not very extended, and is not admissible with respect to long pipes. It was found by Bossut that water has its celerity diminished eight times by passing through a tube of one inch in diameter and 204 feet long. In order to obtain the greatest discharge from a pipe, it is necessary that the inside be smooth, the width uniform, and sudden bendings avoided. The want of evenness of surface impedes the motion of the fluid, which is further obstructed by any violent change of celerity or direction. Whether the channel be contracted or enlarged, the change is unavoidably attended with a proportional loss of impulsion. Any sharp flexure of the pipe or conduit will occasion a still greater waste of the inciting force. It is also found that a curvilineal pipe discharges less water than a rectilineal one of the same length, and that when the flexures are vertical the quantity discharged is less than when they are horizontal. When a large pipe has a number of contrary flexures, the air sometimes mixes with the water, and occupies the highest parts of each flexure, by which means the velocity of the fluid is greatly retarded, and the quantity discharged much diminished.

When liquids flow through very small orifices, or capillary tubes, the resistance is greatly augmented, and the rules which apply to orifices or pipes of considerable diameter no longer hold good. In this case the celerity depends very considerably on the temperature of the liquid. Thus pure water, at a temperature near the boiling point, is found to flow through a capillary tube five times faster than when the temperature is near the freezing point. Alcohol is found to flow six times faster when the temperature is raised 124 degrees. Quicksilver is less affected, but it endures heat through a wider range.

With respect to water running in open channels, or in rivers, the resisting forces are so numerous, and of so irregular a nature, that it is of little use to attempt to deduce their effect from any general principles. In all cases the velocity is increased by the depth of the stream and of the declivity on which it runs to a certain limit; that is, till the resistance, which increases with the velocity, becomes equal to the acceleration, when the motion of the stream becomes uniform. The resistance of course depends much on the evenness of the bottom and sides of the channel. The greatest velocity of a river is at the surface and in the middle of the stream, from which it diminishes towards the bottom and sides, where it is least. It has been found by experiment that if from the square root of the velocity in the middle of the stream, expressed in inches per second, unity be subtracted, the square of the remainder will be the velocity at the bottom. Thus, let v = the velocity at the surface in the middle of the stream, then the velocity at the bottom will be expressed by $(\sqrt{v} - 1)^2 = v - 2\sqrt{v} + 1$. It has also been found by experiment that the mean velocity (or that with which, were the whole stream to move, the discharge would be the same with the real discharge) is equal to half the sum of the greatest and least velocities, as computed by the above formula. The mean velocity is therefore $v - \sqrt{v} + \frac{1}{2}$. These formulæ are deduced from the experiments of Du Buat. (See *Playfair's Elements of Natural Philosophy*.)

When the sections of a river vary, the quantity of water remaining the same, the mean velocities are inversely as the areas of the sections; but when the river receives a permanent addition, the velocity is immediately increased. The effect of this is to augment the action on the sides and bottom, in consequence of which the width is augmented, and sometimes, though more rarely, the depth. This increase of width, by multiplying the points of resistance, again reduces the velocity, till an equilibrium is established between the velocity and resistance; after which the bed of the river changes only by insensible degrees. *See* River.

The determination of the force with which a liquid in motion strikes a solid at rest, and the force necessary to propel a solid immersed in a liquid, is another important part of hydraulics; though, of the general principles hitherto deduced from theory, there are only a very small number which afford a tolerable approximation to the results of experiment. The force of a stream must be regarded as compounded of the force of each particle and of the number of particles that strike in a given time. Now the force of each particle is proportional to the velocity with which it impinges; and the number of particles that strike in a given time is also proportional to the velocity of the stream, supposing its section to remain the same; hence the whole force of the stream is as the

square of the velocity. It follows that if the plane struck by a stream be itself in motion, the impulse will be as the square of the difference of their velocities; and if a stream strike obliquely on a plane, its force is less than if it struck directly on the same plane in the ratio of the cube of the sine of the obliquity to the cube of the radius. But it would appear from experiment that this last consequence only holds true when the angle of inclination is greater than 60 degrees. It might seem (and it is agreeable to theory to suppose) that a plane moving against a liquid at rest with a given velocity, would receive the same impulse as if the liquid were to move with that velocity and the plane to remain at rest. This, however, is not confirmed by experience, which proves that the resistance of a liquid to a body in motion is considerably less than the percussion of the liquid moving with the same velocity against the body at rest. The difference arises from the action of the liquid on the hinder part of the moving body, by which the resistance is in some degree counteracted. But the resistance depends very materially on the figure of the body, and the relation of its length to its breadth. A conical-shaped body, when its length is considerable, is more easily drawn through the water with its broad than with its narrow end foremost. In general, it is found that whatever tends to diminish the adhesion of the body to the liquid tends also to diminish the resistance. A wedge which has its sides rubbed with grease is found to move more freely through the water; hence the great benefit derived from sheathing a ship's bottom with copper. *See* RESISTANCE.

The following are some of the best works on this subject:—Bossut, *Traité Elémentaire d'Hydrodynamique;* Belidor, *Architecture Hydraulique;* Du Buat, *Principes d'Hydraulique:* Prony, *Nouvelle Architecture Hydraulique*, and *Récherches Physico-Mathématiques sur la Théorie des Eaux courante; Experimental Inquiry concerning the Motion of Fluids*, by J. B. Venturi, translated by W. Nicholson; *Ency. Brit.*, articles "Hydrodynamics," "River," &c.

HYDRIO'DIC ACID. A gaseous compound of hydrogen and iodine, obtained by the mutual decomposition of iodide of phosphorus and water. It is composed of 126 iodine + 1 hydrogen; and its equivalent, therefore, is 127. The specific gravity of this gas is 4·4. One hundred cubic inches weigh 136 grains. It is rapidly absorbed by water, furnishing a sour, colourless, and dense liquid, which soon becomes brown by exposure to air, in consequence of the evolution of a little free iodine. It is instantly decomposed by chlorine, which abstracts the hydrogen to form hydrochloric (muriatic) acid, and sets the iodine free.

HYDROBRO'MIC ACID. A gaseous acid composed of 78 bromine + 1 hydrogen. It is obtained by the mutual decomposition of bromide of phosphorus and water.

HYDROCA'RBON. A term applied by chemists to compounds of hydrogen and carbon. These elements unite in several proportions, and form a variety of curious definite combinations, which are commonly termed *hydrocarburets.*

HYDROCA'RBURETS. Compounds of hydrogen and carbon. There appear to be several definite combinations of these elements; among them the following deserve especial notice:—1. *Light carburetted hydrogen gas*, which is the *firedamp* of coal mines and of marshes: 100 cubic inches weigh about 17·4 grains. It consists of 2 atoms of hydrogen = 2, and 1 of carbon = 6; its equivalent is 8. It burns with a pale blue flame. 2. *Olefiant gas*, which is formed during the distillation of equal measures of alcohol and sulphuric acid: 100 cubic inches weigh 30·5 grains. It is composed of 2 atoms of hydrogen = 2, and 2 of carbon = 12; and its equivalent, therefore, is 14. It burns with a bright white flame. Coal gas consists of a mixture of these two hydrocarbons. The term *olefiant gas* is derived from the action of chlorine upon it, which, when mixed with the gas over water, gradually condenses it into a liquid looking like oil, which is a *hydrochloride of carbon.* 3. *Quadricarburetted hydrogen*, which is produced during the destructive distillation of oil (Faraday, *Annals of Philosophy*, xxvii. 44.), and which is a vapour condensable at 0°, of which 100 cubic inches weigh 61·2 grains. It consists of 4 atoms of hydrogen = 4, and 4 of carbon = 24; and its equivalent is 28. It burns with a dense and very smoky flame. This compound has also been called *etherine*, 1 volume of the vapour of *ether* being constituted of 1 volume of quadrihydrocarbon and 1 of water vapour. 4. *Bicarburet of hydrogen*, obtained, like the last, from the volatile products formed during the destructive distillation of whale oil. When the quadrihydrocarbon has been distilled off from the more volatile portion, that which remains yields a product which congeals at 0°. It is a brittle white solid at that temperature: 100 cubic inches of its vapour weigh 85·3 grains, and it consists of 3 atoms of hydrogen = 3, and 6 of carbon = 36; its equivalent, therefore, is 39. These are the principal forms of hydrocarbon which have been satisfactorily identified: they all afford carbonic acid and water when burned in a sufficiency of oxygen; and the proportions in which these are formed, together with the specific gravities of their respective vapours, furnish the data upon which their composition is estimated. *See* NAPHTHA and NAPHTHALMI.

HYDROCA'RDIA. Dropsy of the pericardium.

HY'DROCE'LE. (Gr. ὑδωρ, and κηλη, *a tumour.*) A collection of watery or serous fluid in the tunica vaginalis testis.

HYDROCE'PHALUS. (Gr. ὑδωρ, and κεφαλη, *the head.*) Dropsy of the brain, or water in the head. The acute form of this disease is almost limited to childhood; it is marked by febrile symptoms, pain of the head, and in very young children enlargement of it. The eyes are irregularly directed and the pupil dilated. The eyes are not perfectly closed in sleep, and there appears a degree of delirium, as far as can be judged of in children: coma, convulsions, and paralysis are frequent consequences. The ventricles of the brain are the chief seat of the watery accumulation. Bleeding from the temporal artery or jugular vein, cold applications to the head, and brisk purgatives with calomel, are the leading remedies.

HY'DROCHARA'CEÆ. (Hydrocharis, one of the genera.) A natural order of floating Endogens, inhabiting Europe and some other places, known by their tripetaloideous flowers with an inferior ovary. They agree with *Alismaceæ* in habit and in want of albumen, but differ in their carpels being definite in number. They are not of any known use, but many of the species are handsome when in flower.

HYDROCHLO'RIC ACID. A gaseous compound of 1 atom of chlorine = 36, and 1 atom of hydrogen = 1; the equivalent, therefore, of the hydrochloric acid is = 37. *See* MURIATIC ACID.

HY'DROCO'RISÆ. (Gr. ὑδωρ, and κορις, *a bug.*) The name of a tribe of Hemipterans, including the water-bugs; these differ from the *Geocorisæ*, or land-bugs, in having minute antennæ inserted beneath the eyes. This tribe includes the water-scorpions (*Nepidæ*), and the boat-men (*Notonectidæ*).

HYDROCYA'NIC ACID. (Gr. ὑδωρ, and κυανος, *blue.*) This highly noxious compound was first discovered in Prussian blue, and hence called *Prussic acid.* It is best obtained by gently heating in a small retort a mixture of three parts of cyanuret of mercury and two of hydrochloric acid: the evolved vapours should be passed through a tube containing fragments of marble, in order to absorb any hydrochloric acid that may chance to distil over, and ultimately condensed in a receiver immersed in a freezing mixture. The hydrocyanic acid is a colourless liquid, having a very strong odour, resembling that of bitter almonds; its specific gravity at 45° is 0·7. It boils at 80°, and freezes at 0°. Dissolved in a large quantity of water, it imparts to it the smell and taste of laurel or bitter almond water: it is intensely poisonous. It consists of 26 cyanogen + 1 hydrogen, or of 14 nitrogen + 12 carbon + 1 hydrogen; and its equivalent is 27.

HYDRODYNA'MICS (Gr. ὑδωρ, and δυναμις, *power*), is the science which applies the principles of dynamics to determine the conditions of motion or rest in fluid bodies. It is usually divided into two branches; namely, *hydrostatics*, which explains the laws of the equilibrium, pressure, and cohesion of fluids; and *hydraulics*, which explains the laws of their motion, together with the machines in which they are chiefly concerned. Though the term *hydrodynamics* is sometimes applied generally to fluids of all kinds, it is more usually restricted to the non-elastic or incompressible fluids, as water, mercury, &c.; in which case the science which treats of the equilibrium of the compressible and elastic fluids, like air, is called *aerostatics*, and that which treats of their motion *pneumatics*

Hydrodynamics, though a science of immense importance in its applications to the various purposes of life, was not cultivated to any extent by the ancients, all their knowledge of the doctrine of fluids being limited to a few propositions regarding the pressure and equilibrium of water. Archimedes, indeed, established the general principles which serve as the foundation of hydrostatics, in his treatise *De Insidentibus Humido;* and Ctesibius and Hero, who flourished at Alexandria about 120 years after Christ, invented the fountain of compression, the syphon, and the forcing pump. Julius Frontinus, who was inspector of the public fountains at Rome in the reigns of Nerva and Trajan, wrote a work on the Roman aqueducts, and the modes of distributing water then in use; but he appears to have been unacquainted with the law of the velocities of running water depending on the depth. The first modern treatise on hydrodynamics was published in 1639 by Castelli, a disciple of Galileo, entitled *Della Misura dell' Acque Correnti*, and contains a satisfactory explanation of various phenomena in the motion of fluids. Torricelli discovered the important property that the velocities of fluids issuing through an orifice are as the square roots of the pressures; Mariotte, in his *Traité du Mouvement des Eaux*, employed the principle of Torricelli, and explained the

discrepancy between theory and observation by ascribing it to the retardation of the water's velocity arising from friction. Guglielmini was the first who treated of the motion of water in rivers and open canals. The subject of the oscillation of waves, one of the most difficult in the whole science, was first investigated by Sir Isaac Newton, who determined the duration of the oscillations, and thence concluded that the velocities of waves formed on the surface of water are in the subduplicate ratio of their size. He was also the first who observed the contraction in the vein of a fluid issuing through an orifice, and regarded the contracted section as the true orifice, by which the theory was rendered more conformable to experience. The *Hydrodynamica* of Daniel Bernoulli was published in 1738. His theory of the motion of fluids consists in supposing, 1st, that the surface of a fluid in a vessel, while emptying itself by an orifice, remains always horizontal; and 2d, that if the fluid mass is conceived to be divided into an infinite number of horizontal strata, all the strata remain parallel, and descend vertically with velocities inversely proportional to their breadth, or to the horizontal sections of the reservoir. From these suppositions, and by means of the application of the principle of the conservation of living forces, he obtained solutions of the principal problems of hydrodynamics. The mathematical theory of the motion of fluids was farther investigated by John Bernoulli, Maclaurin, and the celebrated D'Alembert; the latter of whom placed it in an entirely new light by the application of Euler's calculus of partial differences. One of the best treatises on hydrodynamics which we possess is that of the Abbé Bossut, in which are given the results of a very extensive set of experiments performed with great judgment and accuracy. Similar experiments, and more extensively varied, were afterwards undertaken by Du Buat, whose *Principes d'Hydraulique*, in three volumes, contains a theory founded solely on the results of experiments. Du Buat was the first who determined experimentally the influence of heat in promoting fluidity. Among other experiments more recently undertaken for the purpose of throwing light on this interesting and difficult subject, we may mention those of Coulomb, of Eytelwein of Berlin, of Bidone of Turin, of General Sabatier of Metz, of Mr. George Rennie, and of Mr. Jardine of Edinburgh, from which some valuable results have been obtained relative to the discharge of water from long pipes.

The analytical theory of hydrodynamics resolves itself into the integration of equations of partial differences, a branch of the calculus which we owe to the illustrious Euler. Euler himself gave the general formulæ for the motion of fluids, founded on the laws of their equilibrium, and thus reduced the whole mechanics of fluid bodies to a single question of analysis. If these formulæ could be integrated, we should be able to determine completely, in every case, all the circumstances of the motion and action of a fluid subjected to the influences of any forces whatever; but such is the difficulty of the subject that the integration, except in a few limited cases, has hitherto resisted the efforts of the greatest mathematicians. Lagrange, in his *Mécanique Analytique*, has deduced the analytical formulæ of the motion of fluids from the principle of virtual velocities, and thus shown that dynamics and hydrodynamics are only branches of one great principle, and results as it were of a single general formula. Laplace, in the *Mécanique Céleste*, has also given the general equations of hydrodynamics, and applied them to the questions of the figure of the earth and the tides. Since the days of those illustrious mathematicians, the theory has been illustrated with reference to applications to particular cases by Poisson, Cauchy, Navier, Challis, and others; but it cannot be said to have received any material extension.

Treatises on hydrodynamics are very numerous. Besides the works of Lagrange and Laplace, and the others above mentioned, we would refer the student to *Bossut's Hydrodynamique; Poisson's Mécanique; Moseley's Elementary Treatise on Hydrostatics and Hydrodynamics.* (*See* HYDROSTATICS and HYDRAULICS.)

HYDROFLU'ORIC ACID. A highly corrosive and very volatile liquid, obtained by distilling in leaden or silver vessels a mixture of 1 part of *pure* fluor spar in fine powder with 2 of sulphuric acid. This compound acts vehemently upon glass and all silicious combinations; it is probably a compound of 18 fluorine + 1 hydrogen.

HY'DROGEN. (Gr. ὑδωρ, and γεννααιν, *to generate.*) This important element is only known to us in the gaseous or permanently elastic form. It was formerly called *inflammable air*, and was sometimes considered as identical with *phlogiston*, or the matter of heat. It is usually procured by the action of sulphuric acid and zinc or iron upon water, or by passing the vapour of water over red-hot iron. Pure hydrogen is a colourless, tasteless, and inodorous gas. 100 cubic inches at mean temperature and pressure weigh 2·13 grains; so that its specific gravity compared with air is as 69 to 1000, and it is exactly 16 times lighter than oxygen. It burns in contact with air with a pale blue flame; and when mixed with three or four times its volume of air, or with half its volume of pure oxygen, and inflamed, it burns rapidly, and in the latter case with violent explosion. The only product of this combustion is *water*, which is thus shown to consist of 1 part by weight of hydrogen with 8 of oxygen; so that upon this datum the number 8 becomes the equivalent of oxygen, and 9 that of water. Hydrogen is not absorbed by water, and animals soon die when confined in it.

HYDRO'GRAPHY. (Gr. ὑδωρ, and γραφω, *I write.*) The description of the waters which exist at the surface of the earth, particularly with reference to the bearings of the coasts, the depths, currents, and other circumstances required to be known for the purposes of navigation. This term implies the same thing with regard to the sea that geography implies with regard to the land. *Hydrographical charts* or *maps* are projections of some part of the ocean, in which the rhumbs, meridians, parallels, &c., with the coasts, capes, rocks, shallows, &c., are laid down for the uses of navigation.

HYDRO'GURETS, or HY'DURETS. Compounds of hydrogen with metals, &c.

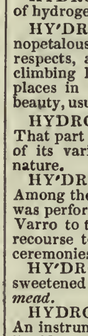
HY'DROLEACEÆ, are a small natural order of Monopetalous Exogens, resembling *Boraginaceæ* in some respects, and *Convolvulaceæ* in others; not, however, climbing like the latter. They chiefly inhabit watery places in tropical climates, and have flowers of some beauty, usually belonging to the Cyanic series.

HYDRO'LOGY. (Gr. ὑδωρ, and λογος, *discourse.*) That part of natural history which treats of water, and of its various properties and modes of existence in nature.

HY'DROMANCY. (Gr. ὑδωρ, and μαντεια, *prophecy.*) Among the ancients, a method of divination by water. It was performed in various ways. Its origin is ascribed by Varro to the Persians; and Numa is said to have had recourse to it for instruction how he should settle the ceremonies of religion.

HY'DROMEL. (Gr. ὑδωρ, and μελι, *honey.*) Water sweetened with honey, which, when fermented, forms *mead.*

HYDRO'METER. (Gr. ὑδωρ, and μετρον, *measure.*) An instrument for determining the specific gravities of liquids, and thence the strengths of spirituous liquors; these being inversely as their specific gravities. Various instruments of different forms have been proposed for ascertaining readily the specific gravities of fluids; but as Sikes's hydrometer is directed by act of parliament to be used in collecting the revenue of the United Kingdom, it may be considered as more deserving of description than any of the others. This instrument is represented in the annexed figure.



A B is a flat stem, divided on both sides into eleven equal parts, each of which is again subdivided into two. The stem carries a hollow brass ball B C, in which is fixed a conical stalk C D, terminating in a pear-shaped bulb D. Eight different weights of a circular form, and marked with the numbers 10, 20, 30, 40, 50, 60, 70, and 80, are cut in the manner represented at W, so that they can be placed on the stalk C D. When the strength of spirits is to be measured, one of the circular weights is placed on C D, which is found by trial to be capable of sinking the ball so far that the surface of the liquid cuts the stem at one of the divisions between A and B. The number of this division is then observed, and also the temperature of the liquid; and the corresponding strength per cent. of the spirit is then found in a table which accompanies the instrument.

Another easy method of determining the densities of different liquids, frequently practised, is by means of a set of glass beads previously adjusted and numbered. Thrown into any liquid, the heavier balls sink and the lighter float at the surface; but one of them approaching the density of the liquid will be in a state of indifference as to buoyancy, or will float under the surface. The number on this ball indicates, in thousandth parts, the specific density of the liquid.

HY'DROME'TRA. (Gr. ὑδωρ, and μητρα, *the womb.*) Dropsy of the uterus.

HY'DROME'TRIDÆ. (Gr. ὑδωρ, and μητρα, *a birth-place.*) A family of *Geocorisæ*, or land-bugs, but of aquatic habits; not, however, living in water, but frequenting the surface.

HY'DROPE'RICA'RDIUM. (Gr. ὑδωρ, and περικαρδιον.) Dropsy of, or an unnatural accumulation of watery fluid in, the sac of the heart.

HY'DROPERSULPHU'RIC ACID, or BISULPHURET OF HYDROGEN. A compound of 2 equivalents of sulphur and 1 of hydrogen: its equivalent is 33.

HY'DROPHANE. (Gr. ὑδωρ, and φαινω, *I shine.*) A

variety of opal, which is white and opaque when dry, but becomes transparent in water.

HYDRO'PHIDES. (Gr. ὑδωρ, and οφις, *a serpent.*) A name applied to the section of *Ophidians*, including the water-snakes. These are principally distinguished by having the tail compressed or flattened sideways, for the purpose of swimming. They are armed with poison fangs; but these are of small size, and are associated with a row of non-venomous maxillary teeth.

HYDRO'PHILIDÆ. (Gr. ὑδωρ, and φιλεω, *I love.*) A family of Pentamerous Coleopterans, including those species which have short clavate antennæ, long and slender palpi, mandibles bidentate at the tips; body oval and convex; and the hind-legs often ciliated. The *Hydrophilidæ*, like the *Dyticidæ*, are aquatic beetles, and have wings by which they can transport themselves from one piece of water to another; but they are vegetable-feeders, and are less active in their movements than the predatory water-beetles. The family includes many genera. The typical species, *Hydrophilus caraboides*, is common in the stagnant ponds and ditches of this country.

HY'DROPHO'BIA. (Gr. ὑδωρ, and φοβεομαι, *I fear.*) A disease remarkably characterized by alarm at the approach of water, and caused by the bite of a mad dog or other rabid animal; but it does not appear capable of being communicated by the human subject. At some indefinite period after the bite, and often long after all local injury has healed, itching and pain in the bitten part, heaviness, great restlessness and uneasiness, and mental alarm ensue, followed by pains about the neck, sense of choking, and great irritability and horror at any attempt to drink, although solid food can generally be swallowed. Fever, vomiting, excessive thirst, spitting of viscid saliva, and difficult respiration then come on, with irregular pulse and convulsions, under which the sufferer sinks more or less rapidly according to the strength of his constitution. Delirium sometimes precedes death, but not always; in many instances the judgment appears unaffected. It unfortunately happens that nothing in the way of cure, and little even as palliation, has been successfully effected in this disease; but there appears little doubt that the timely application of preventive measures has been successful, and of these the amputation or excision of the bitten part, and the application of caustics to it, or both united, are most to be relied on; and the sooner they are resorted to the better the chance of success, but it appears that they may be effective any time before the appearance of symptoms. Among caustics, the nitric acid is perhaps the most effective. It energetically acts upon and decomposes all animal matter, and fluids more especially; and if applied very soon after the bite, can scarcely fail to be effective: it also penetrates the wound, and forms a sloughing sore. The appearance of madness in dogs, in its early stages at least, is unfortunately not very well defined, nor always easily distinguishable from their other maladies: whether the bite is less dangerous before they become evidently rabid than afterwards, seems to be doubtful. In general the animal is observed to be unusually dull and unsociable, refuses food, hangs his head, and appears drowsy: he flies at strangers, but usually recognizes his master, though with great comparative indifference. Afterwards his breathing is quick and heavy; frothy matter runs from his mouth; he walks slowly, but occasionally runs and starts forward; at length he forgets his master, often falls down, flies at every body in his way, grows furious, and in four-and-twenty or thirty hours dies.

HYDROPHYLLA'CEÆ. (Hydrophyllum, one of the genera.) A natural order of herbaceous Exogens, inhabiting America; very near to *Boraginaceæ*, from which they are known by their one-celled, many-seeded fruit, and many other characters. Some *Polemoniaceæ* have the habit of this order. Some of the species of *Eutoca* and *Phacelia* are cultivated on account of their pretty flowers.

HY'DROPHYTES. (Gr. ὑδωρ, and φυτον, *a plant.*) Plants which thrive in water; a name confined by botanists to Algaceous plants found in fresh water. It has been remarked by Mr. Lyell (*Principles of Geology*) that the number of hydrophytes is very considerable, and their stations more varied than could have been anticipated; for while some plants are daily covered and uncovered by the tide, others live in abysses of the ocean at the extraordinary depth of 1000 feet; and although in such situations there must reign darkness more profound than night, at least to our organs, many of these vegetables are highly coloured.

HY'DROPS. (Gr. ὑδωρ.) Dropsy. An unnatural accumulation of fluid in the cellular membrane or cavities of the body.

HY'DROPTHA'LMIA. (Gr. ὑδωρ, and οφθαλμος, *the eye.*) Dropsy of the eye.

HYDRORACHI'TIS. (Gr. ὑδωρ, and ῥαχις, *the spine.*) A tumour upon the spine of infants; at first of a blue colour, but afterwards becoming translucent; it is attended with paralysis of the lower limbs, and usually fatal in its consequences.

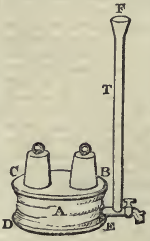
HY'DRO-SALTS. Salts of the hydracids.

HY'DROSCOPE. (Gr. ὑδροσκοπιον, from ὑδωρ and σκοπεω, *I view.*) An instrument anciently used for measuring time by means of the flowing of water through a small orifice. It consisted of a cylindrical tube, conical at the bottom. The cylinder was graduated; and as the water trickled out at the apex of the cone, its surface became successively contiguous to the divisions marked on the cone, and thereby pointed out the hour.

HYDROSTA'TICA. (Gr. ὑδωρ, and στaω, *I stand.*) The name of an order of *Acalephes*, including those which have one or more air-vessels appended to their body.

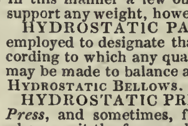
HYDROSTA'TIC BALANCE. A balance for weighing substances in water, for the purpose of ascertaining their specific gravities. *See* BALANCE.

HYDROSTATIC BELLOWS. An apparatus for illustrating the *hydrostatic paradox*, or that peculiar property of liquids in virtue of which they transmit pressure equally in every direction. In the annexed figure B C and D E are two flat boards united by leather or flexible cloth A, water-tight. A short tube fitted with a stop-cock communicates with the interior of the bellows, by which the liquid may be discharged. From the short tube a long tube T rises perpendicularly, and terminates in a funnel F. The upper board B C is loaded with weights, which press it against the lower board D E. On pouring water into the funnel F it will descend through the tube T, and enter between the boards; and by continuing the supply a column will be formed in the tube, the weight of which, transmitted through the water in the bellows, will raise and support the weights on the board. The load which may be thus raised is easily determined. Every portion of the surface of the board B C, equal in area to the section of the tube, is pressed upwards by a force equal to the weight of the water in the tube above the level of B C. Hence, if the section of the tube T is one square inch, and the surface of the board B C is 1000 square inches, then a column of water in T weighing one pound will sustain a weight on the board of 1000 pounds. In this manner a few ounces of water may be made to support any weight, however great. *See* HYDROSTATICS.



HYDROSTATIC PARADOX. A term frequently employed to designate that principle in hydrostatics according to which any quantity of water, however small, may be made to balance any weight, however great. *See* HYDROSTATIC BELLOWS.

HYDROSTATIC PRESS, also called the *Hydraulic Press*, and sometimes, from the name of the engineer who gave it the form under which it is now constructed, and brought it into general use, *Bramah's Press*, is a machine by means of which an enormous force of pressure is obtained through the medium of water. The principle is the same as that of the *hydrostatic bellows;* from which, indeed, it only differs by the substitution of a strong forcing pump for the long tube, and a barrel and piston for the leather and boards. It consists of a short and very strong pump-barrel A B, with a solid piston C of proportionate strength, which is pushed upwards against the thing to be compressed by water driven into the barrel beneath it at F from the small forcing pump E. If the small pump have only one thousandth of the area of the large barrel, and if a man by means of its lever handle D press its piston down with a force of five hundred pounds, the piston of the great barrel, in virtue of the hydrostatic principle of equal pressure in all directions, will rise with a force of a thousand times five hundred pounds, or more than 200 tons. The hydrostatic press is applied to a great variety of useful purposes; for compressing bales of goods, as paper, cotton, wool, tobacco, &c.; for expressing oils from seeds, raising weights, uprooting trees, &c.



HYDROSTATICS (Gr. ὑδωρ, and στaω, *I stand*), is the science which explains the properties of the equilibrium and pressure of liquids. It is the application of statics to the peculiar constitution of water or other bodies existing in the perfectly liquid form.

The whole doctrine of the equilibrium and pressure of liquids is deduced from the following fundamental law:— "When a liquid mass is in equilibrium under the action of forces of any kind, every molecule of the mass sustains an equal pressure in all directions." This law is derived from the very nature of a liquid body, which is such that

all its particles are independent of each other, and perfectly moveabel in every direction; whence if any particle sustained a greater pressure in one direction than another, it would necessarily, by reason of the absolute facility of motion with which it is endowed, give way and move towards that part where the resistance is least, and consequently there would not be equilibrium.

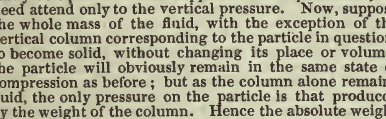
One of the most obvious consequences of the above law is, that the surface of a liquid when at rest in an open vessel, and acted upon by no other force than gravity, is horizontal, or perpendicular to the direction of gravity. If the directions of gravity are parallel, the surface will consequently be a plane; if they converge to a point, the surface of the liquid will be a portion of a sphere. Stagnant water at the surface of the earth, therefore, assumes the spherical figure; but by reason of the magnitude of the sphere the curvature of any small portion of it is insensible, and the surface may be regarded as a plane. A ring surrounding the earth would bend away from a perfectly straight line only eight inches in a mile.

If a free communication is made between two or more vessels containing a liquid by pipes or tubes or otherwise, the surface of the liquid when in equilibrium will always stand at the same level. Let A B, A′ B′ be two tubes, united by a third B B′ placed in the horizontal position, and suppose water to be poured into one of the tubes at A; it will pass along the tube B B′, and rise in B′ A′ and B A simultaneously, its surfaces at A and A′ always remaining level, or at equal vertical heights above B B′. This property is familiarly illustrated in the case of a tea-pot, or any vessel having a spout.

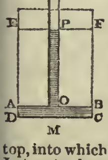
The liquid contained in a vessel being at rest, and subjected to the action of gravity only, any particle of it is pressed in all directions (vertically, horizontally, or obliquely) by a force which is equal to the weight of the vertical column of the liquid incumbent on it. This important proposition may be demonstrated in the following manner: — As the pressure in all directions must necessarily be equal from the supposition of equilibrium, we need attend only to the vertical pressure. Now, suppose the whole mass of the fluid, with the exception of the vertical column corresponding to the particle in question, to become solid, without changing its place or volume, the particle will obviously remain in the same state of compression as before; but as the column alone remains fluid, the only pressure on the particle is that produced by the weight of the column. Hence the absolute weight of the column forms the measure of the pressure sustained by the particle in all directions when surrounded by the liquid.

Instead of a particle of the liquid itself we may consider the column to rest on an indefinitely small portion of the bottom or the sides of the vessel in which it is contained, and it will follow that the pressure on an indefinitely small portion of the area at any point of the bottom or sides is perpendicular to the plane of that area, and equal to the weight of a vertical column of the liquid standing on it as a base and reaching to the surface. Hence the whole pressure sustained by any finite portion of the bottom or sides of the vessel is equal to the weight of a column of the liquid having for its base the surface pressed on (extended into a plane if necessary), and for its altitude the distance of the centre of gravity of that surface from the surface of the liquid.

From this proposition it obviously follows that the pressure on the bottom of the vessel depends only on the magnitude of the bottom and the depth of the liquid, and is entirely independent of the form of the sides and



of the quantity of liquid in the vessel. Suppose the three vessels A, B, and C, to have the areas of their bottoms equal, and that the fluid stands in each to the same depth; then the pressure on the bottom of each vessel is the same, and equal to the weight of the liquid which would be contained in a vessel having an equal bottom and its sides perpendicular.



This proposition gives rise to consequences which at first view appear absurd, and has hence been called the hydrostatic paradox. Let A B C D be a close vessel with a small hole O in the top, into which a narrow tube O P is screwed water-tight. Let water be poured into the tube till the vessel A B C D is filled, and the water stands in the tube at the level P. According to the principle just established, the pressure on the bottom C D is proportional to the depth P M, or in fact equal to the weight of water which would fill a vessel of the magnitude E D C F. Now this is the case, however shallow the vessel A B C D, and however narrow the tube P O may be; and hence a very small quantity of water may be made to exercise a pressure of any amount, however great, on the bottom or sides of the vessel containing it.

The whole pressure on the top A B of the vessel, and tending to raise it, is equal to the weight of the water in the tube P O, increased in the ratio of the area of A B to the area of a section of the tube. Suppose a section of the tube to be one square inch, and the area of A B to be 100 square inches; then a column of water O P, whose weight is one pound, will exert a pressure on A B equal to 100 pounds. It is obvious that the pressure in the narrow tube P O may be produced not merely by the addition of water, but by the application of any kind of force, such as the working of a piston, &c.; and if the bottom or lid of the vessel A B C D be made moveable, the pressure on either may be brought to bear on one point of an external body, and produce an enormous compression. It is on this principle that the very useful engine, the *hydrostatic press*, is constructed. *See* HYDROSTATIC PRESS and HYDROSTATIC BELLOWS.

Many striking phenomena of the natural world are referable to this principle, and it has extensive application in engineering. If the smallest quantity of water should lodge to a considerable height in the gravel, sand, or loose earth behind a wall or embankment, it would exert a lateral pressure sufficient to push the solid materials from their base. Hence a sudden shower often occasions great devastation. The same principle also regulates the construction of pipes for the supply of water to cities. The pressure acting on the inner surface of the pipe, and tending to burst it, being proportional to the depth below the level of the reservoir, the parts of the pipe much below that level must have a greater strength than is necessary at a higher situation. A pipe, the diameter of whose bore is 4 inches, has an internal circumference of about 1 foot; and the internal surface of 1 foot of such a pipe will be 1 square foot, or 144 square inches. If such a pipe were 140 feet below the level of the reservoir, it would sustain a bursting pressure amounting to about 60 pounds on every square inch of its surface; for a column of water, the area of whose section is one square inch, and of which the height is 27·727, or nearly 28 inches, weighs one pound; and 28 inches are contained 60 times in 140 feet. Hence a piece of the pipe 1 foot long will sustain 144 times this pressure, that is, a bursting pressure of 8640 pounds. This exceeds considerably that which is produced in any high-pressure steam engine.

Weight of Bodies immersed in Liquids. — A body immersed in a liquid is pressed upwards by a force equal to the weight of the liquid it displaces; and the difference between the absolute weight of a body and its weight when entirely immersed, is the same with the weight of a quantity of the liquid equal in bulk to the body. This proposition, which is capable of strict demonstration from the fundamental property of fluids, may be illustrated as follows: — Suppose any interior portion of a liquid to become solid; it would evidently remain in the same state of indifference or equilibrium as before. It must, therefore, be borne up by the vertical pressure of the liquid with a force just equal to its weight, or, which is the same thing, to the weight of the liquid whose place it occupies. And if we conceive this congealed mass to have its weight augmented or diminished, it will be pulled downwards or upwards by the difference between its new weight and the weight of an equal bulk of the liquid. Substitute any solid body instead of this block of ice, and the loss of weight it sustains by the immersion will be equal to that of the volume of liquid it displaces.

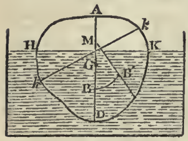
On this principle is founded the method of ascertaining the relative densities or *specific gravities* of different bodies. The specific gravity of a body is the ratio of its weight to the weight of an equal bulk of water. Let, therefore, W be the weight of a body in air, and W′ its weight in water; then $W - W'$ is the weight of a quantity of water equal in bulk to the body, and $\frac{W}{W - W'}$ is its specific gravity. The specific gravities of bodies are therefore found by weighing them first in air and then in water. *See* GRAVITY, SPECIFIC.

Solid Bodies floating on Liquids. — The equilibrium of solid bodies floating on liquids, a subject discussed by Archimedes in his treatise *De Humido Insidentibus*, is an important part of hydrostatics, in consequence of its relation to the construction and stowage of ships. A body placed on a fluid specifically heavier than itself, will sink so far that the weight of the fluid displaced is equal to the whole weight of the body; and when it assumes the position of equilibrium, the line which joins the centre of gravity of the body and the centre of buoyancy (which

is the same as the centre of gravity of the immersed part supposed to be homogeneous) is perpendicular to the surface of the water, or the horizon.

The centre of gravity of a body is a fixed point relatively to the body itself; but the centre of buoyancy, which depends on the figure of the immersed part, will change its place when the figure or relative situation of the immersed part undergoes any alteration. It is on the relative situations of the centres of gravity and of buoyancy that the character of the equilibrium of a floating body depends; namely, whether it is stable or unstable, or indifferent. If the figure and position of the body be such that on pulling it a little aside from the situation of rest its centre of gravity takes a higher position, the body has a tendency to redress itself, and the equilibrium is stable. On the contrary, if by a slight change of position the centre of gravity comes to occupy a lower place, the body will not return to the position of equilibrium, but will be overturned or upset. In this case the equilibrium was unstable. But a body may be so constituted (for example, a homogeneous sphere, or a cylinder floating with its axis horizontal) that in every position the centres of gravity and of buoyancy are in the same vertical line. In this case the equilibrium cannot be disturbed, and is called the equilibrium of indifference, the body having no tendency to maintain one position more than another.

To illustrate this, and to show at the same time the circumstances on which the stability of the equilibruim depends, let A H D K be a body floating on water, and let H K be the line of floatation; also let G be its centre of gravity, and B its centre of buoyancy, which will be in the same vertical with G when the body is at rest, and will obviously be below G. The body is now pressed down by its own weight collected at G,



and pushed up in the opposite direction by an equal force at B. Suppose it to be drawn aside from the position of rest till the water line comes into the position *h k;* the centre of buoyancy B will now be transferred to B′, and the line of support will be a line passing through B′ perpendicular to the surface of the water. Let this line meet the principal axis A D in M; then the equilibrium will be stable or unstable according as M is above or below G, the centre of gravity. If M is above G, the vertical thrust tends to redress the body and restore the equilibrium; but if the vertical B′ M meets the principal axis below G, the body will be pushed more aside till it is overset. The point M possesses several remarkable properties. Its position in the axis A D remains unaltered when the body is drawn aside from the position of equilibrium; and it limits the greatest elevation which the centre of gravity can have in order that the equilibrium may be stable. It was denominated by Bouguer the *metacentre*, and its position may be determined in all cases where the figure and specific gravity of the floating body are given.

As the stability of a floating body depends on the height of the metacentre above the centre of gravity, the construction of a ship should be so regulated, and its cargo so arranged, that the centre of gravity of the whole mass should be at the lowest possible point. Hence the heaviest part of the cargo is stowed away nearest the ship's bottom; and vessels having discharged their cargo must be *ballasted*, in order to give them requisite stability. When a vessel is without a cargo and empty, the weight of the masts and rigging raises the centre of gravity to such a height as to render the equilibrium unstable, or at least renders its stability so small that it cannot be safely subjected to the ordinary pressure on the sails necessary to give motion, and consequently would be altogether incapable of encountering a gale or a heavy sea.

Another important application of the theory of hydrostatics is to the form that ought to be given to the several parts of embankments, dams, the flood-gates of canals, and other works constructed for the purpose of confining or opposing the course of water. This inquiry, which is purely mathematical, is grounded on the principle that the pressure in any lateral point is directly proportional to its vertical depth under the surface of the water. *See* Hydraulics and Hydrodynamics.

HY′DROSULPHATES, or HY′DROSU′LPHURETS. Compounds of hydrosulphuric acid or sulphuretted hydrogen.

HY′DROSULPHU′RIC ACID. Sulphuretted hydrogen. This compound was also called *hydrothionic acid* (from hydrogen, and Gr. θειον, *sulphur*).

HY′DROTHO′RAX. (Gr.) Dropsy of the chest. The symptoms are, difficult breathing when in a recumbent posture, paleness, cough, thirst, swelling of the legs and feet, quick and often irregular or intermitting pulse.

HY′DRUS. (Gr. ὑδωρ, *water*.) A genus of water snakes, characterized by a compressed or laterally flattened tail adapted for swimming; and by having max maxillary teeth, like non-venomous serpents, but wit the first larger than the rest, and grooved for the trans mission of a poison-duct.

The species are confined to the seas of the warmer latitudes.

Hy′drus. The Water Snake; a constellation in the southern hemisphere formed by Lacaille. *See* Constellation.

HYGEI′A. (Gr. ὑγιεια, *health*.) The Goddess of Health, in the Greek Mythology: daughter or wife of Æsculapius, according to the different recitals of genealogists. Her statues (of which the most celebrated was at Sicyon) sometimes represented her attended by a large serpent coiled round her body, and elevating its head above her arm to drink of a cup which she held in her hand. Isis, in Egyptian monuments, appears sometimes in a similar attitude. The employment of the serpent as a mythological symbol of life and health has been by some derived from the history contained in the first chapter of Genesis.

HY′GEINE. That branch of medicine which relates to the means of preserving public health.

HYGRO′LOGY. (Gr. ὑγρος, *moist*, and λογος, *a discourse*.) A medical term, implying the doctrine of the humours or fluids of the body.

HYGRO′METER. (Gr. ὑγρος, and μετρον, *measure*.) An instrument for measuring the degrees of moisture or dryness of the atmosphere.

Variations in the state of the atmosphere with respect to moisture and dryness are manifested by a great variety of phenomena; and accordingly numerous contrivances have been proposed for ascertaining the amounts of those variations by referring them to some conventional scale. All such contrivances are called *hygrometers;* but though the variety of form that may be given to them, or of substances that may be employed, is endless, they may all be referred to two classes; namely, 1st, those which act on the principle of *absorption;* and, 2d, those which act on the principle of *condensation*.

1. *Hygrometers on the Principle of Absorption.* — Many substances in each of the three kingdoms of nature absorb moisture from the atmosphere with greater or less avidity, and thereby suffer some change in their dimensions, or weight, or some of their physical properties. Animal fibre is softened and relaxed, and consequently elongated, by the absorption of moisture. Cords composed of twisted vegetable substances are swollen, and thereby shortened, when penetrated by humidity; and the alternate expansion and shrinking of most kinds of wood, especially when used in cabinet work, and after the natural sap has been evaporated, is a phenomenon with which every one is familiar. Many mineral substances absorb moisture readily, and thereby obtain an increase of weight. Now it is evident that any of these changes, either of dimension or of weight, may be regarded as the measure of the quantity of moisture absorbed, from which the quantity of water existing in the atmosphere in the state of vapour is inferred; but many, indeed the far greater part of them, are so small in amount, or take place so slowly, that they afford no certain indication of the actual state of the atmosphere at any particular moment.

Of the different kinds of hygrometers whose construction depends on change of dimension arising from the absorption of moisture, there are two deserving of notice on account of their historical celebrity, though they are now seldom if at all used where accurate meteorological observations are attempted. One is the *hair* hygrometer of Saussure; the other the *whalebone* hygrometer of De Luc.

Saussure's hygrometer consists of a human hair prepared by boiling it in a caustic ley. One extremity of the hair is fastened to a hook, or held by pincers; the other has a small weight attached to it, by which it is kept stretched. The hair is passed over a grooved wheel or pulley, the axis of which carries an index which moves over a graduated arch. Such is the essential part of the instrument, and it is easy to conceive how it acts. When the surrounding air becomes more humid the hair absorbs an additional quantity of moisture, and is elongated; the counterpoise consequently descends, and turns the pulley, whereby the index is moved towards the one hand or the other. On the contrary, when the air becomes drier the hair loses a part of its humidity, and is shortened. The counterpoise is consequently drawn up, and the index moves in the opposite direction. The accuracy of the indications of this instrument depends on the assumed principle that the expansion and contraction of the hair are due to moisture alone, and are not affected by temperature or other changes in the condition of the atmosphere. Experiment shows that the influence of temperature is not very great; but after all precautions have been taken in preparing the instrument, it is found to be exceedingly irregular in its movements, and subject to great uncertainties. Besides, the substance is soon deteriorated, and will scarcely maintain its properties unimpaired during a single year.

The hygrometer of De Luc consists of a very thin slip of whalebone cut transversely, or across the fibres, and stretched by means of a spring between two points. One end is fixed to a bar, while the other acts on the shorter arm of the index of a graduated scale. When the whalebone absorbs moisture it swells, and its length is increased; as it becomes dry it contracts; and the space over which the index moves by the one or the other of these effects gives the measure of the expansion or contraction, and the corresponding change in the hygrometric state of the atmosphere. The action of this hygrometer appears to be more uncertain than that of Saussure.

The hygrometers which have been proposed on the principle of a change of weight arising from the absorption of moisture, are liable to still greater objections. Changes of weight may indeed be measured with great accuracy by the common or torsion balance; but in the present case they are so small, that the particles of dust which are at all times floating in the atmosphere may produce a great alteration in the results. A great variety of substances which attract moisture have been employed, such as sponge, cotton, bibulous paper, caustic potash, the deliquescent salts, sulphuric acid, &c.; but the indications which they give are deserving of very little credit. Changes of property indicated by the torsion of cords formed of gut, hemp, cotton, &c., and the torsion of certain vegetable fibres, are still more fallacious.

2. *Hygrometers on the Principle of Condensation.*—The instruments of this class are of a far more refined nature than those which we have been describing. In order to give an idea of the general principle on which they depend, let us conceive a glass jar, having its sides perfectly clean and transparent, to be filled with water, and placed on a table in a room where the temperature is, for example, 60°, the temperature of the water being the same as that of the room. Let us next suppose pieces of ice, or a freezing mixture, to be thrown into the water, whereby the water is gradually cooled down to 55, 50, 45, &c. degrees. As the process of cooling goes on, there is a certain instant at which the jar loses its transparency, or becomes dim; and on attentively examining the phenomenon, it is found to be caused by a very fine dew or deposition of aqueous vapour on the external surface of the vessel. The precise temperature of the water, and consequently of the vessel, at the instant when this deposition begins to be formed, is called the *dew point*, and is capable of being noted with great precision. Now this temperature is evidently that to which, if the air were cooled down, under the same pressure, it would be completely saturated with moisture, and ready to deposit dew on any body in the least degree colder than itself. The difference, therefore, between the temperature of the air, and the temperature of the water in the vessel when the dew begins to be formed, will afford an indication of the dryness of the air, or of its remoteness from the state of complete saturation.

But the observation which has now been described is capable of affording far more interesting and precise results than a mere indication of the comparative dryness or moisture of the atmosphere. With the help of tables of the elastic force of aqueous vapour at different temperatures, it gives the means of determining the absolute weight of the aqueous vapour diffused through any given volume of air, the proportion of vapour existing in that volume to the quantity that would be required to saturate it, and of measuring the force and amount of evaporation.

The elastic force of aqueous vapour at the boiling point of water is evidently equal to the pressure of the atmosphere. This may be assumed as corresponding to a column of mercury 30 inches in height. Mr. Dalton, in the fifth volume of the *Manchester Memoirs*, has given the details of a most valuable and beautiful set of experiments, by which he ascertained the elastic force of vapour from water at every degree between its freezing and boiling points in terms of the column of mercury which it is capable of supporting. As the same experiments have since been frequently repeated, and the different results present all the accordance which can be expected in so delicate an investigation, the tension of vapour at the different temperatures may be regarded as sufficiently well determined. Supposing, then, we have a table exhibiting the elasticity or tension corresponding to every degree of the thermometer, the weight of a given volume of vapour, for example a cubic foot, may be determined as follows:—

Steam at 212°, and under a pressure of 30 inches of mercury, is 1700 times lighter than an equal bulk of water at its greatest density, or a temperature of about 40°, and a cubic foot of water at that temperature weighs 437272 grains; the weight, therefore, of a cubic foot of steam at that temperature and pressure is $437272 \div 1700 = 257{\cdot}218$ grains. Hence we may find the weight of an equal bulk of vapour of the same temperature under any other given pressure, suppose 0·56 of an inch; for the density being directly as the pressure, we have 30 in. : 0·56 in. : : 257·218 grs. : 4·801 grs., which is the weight required.

Having found the weight of a cubic foot of vapour under a pressure of 0·56 of an inch, and at the temperature 212°, we may find its weight under the same pressure at any other temperature, suppose 60°. It is ascertained by experiment that all aëriform bodies, whether vapours or gases, expand the 1-480th part of their volume for every accession of temperature equivalent to one degree of Fahrenheit's scale; therefore, reckoning a volume of gas at 32° as unity, its volume at 60° is to its volume at 212° as $1 + \frac{28}{480}$ is to $1 + \frac{180}{480}$; or as 1·058 : 1·375; and the density and weight being inversely as the volume, we have

1·058 : 1·375 : : 4·801 grs. : 6·222 grs.

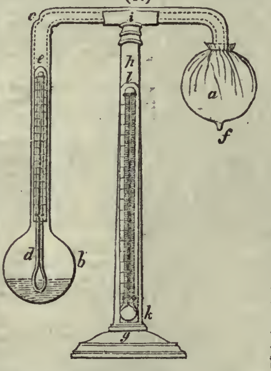
for the weight of a cubic foot of vapour at temperature 60°, and under a pressure of 0·56 of an inch of the mercurial column.

The following table, abridged from *Daniell's Meteorological Essays*, shows the force or tension, weight, and expansion of aqueous vapour, at different temperatures on Fahrenheit's scale:—

Temp.	Force.	Weight of a Cubic Foot.	Expansion.
0	·068	·856	·9334
5	·083	1·034	·9438
10	·098	1·208	·9542
15	·119	1·451	·9646
20	·140	1·688	·9750
25	·170	2·028	·9855
30	·200	2·361	·9959
35	·240	2·805	1·0062
40	·280	3·239	1·0166
45	·340	3·893	1·0270
50	·400	4·535	1·0375
55	·476	5·312	1·0479
60	·560	6·222	1·0583
65	·657	7·230	1·0687
70	·770	8·392	1·0791
75	·906	9·780	1·0895
80	1·060	11·333	1·1000
85	1·235	13·081	1·1104
90	1·430	15·005	1·1208
95	1·636	17·009	1·1312
212	30·000	257·218	1·3749

Having thus explained the principle of the condensation hygrometer, we will now describe one or two of the forms under which it has been most frequently constructed. Daniell's hygrometer is represented in the annexed figure. *a* and *b* are two thin glass balls of 1½ inch diameter,

(1.)



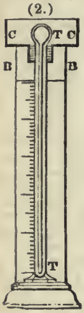
connected together by a tube having a bore about 1-8th of an inch. The tube is bent at right angles over the two balls, and the arm *b c* contains a small thermometer *d e*, whose bulb, which should be of a lengthened form, descends into the ball *b*. This ball having been about two thirds filled with ether, is heated over a lamp till the fluid boils, and the vapour issues from the capillary tube *f* which terminates the ball *a*. The vapour having expelled the air from both balls, the capillary tube is hermetically closed by the flame of a lamp. The other ball *a* is now to be covered with a piece of muslin. The stand *g h* is of brass, and the transverse socket *i* is made to hold the glass tube in the manner of a spring, allowing it to turn and be taken out with little difficulty. A small thermometer *k l* is inserted into the pillar of the stand. The manner of using the instrument is this:—After having driven out all the ether into the ball *b* by the heat of the hand, it is to be placed at an open window, or out of doors, with the ball *b* so situated that the surface of the liquid may be on a level with the eye of the observer. A little ether is then to be dropped on the covered ball. Evaporation immediately takes place, which, producing cold upon the ball *a*, causes a rapid and continuous condensation of the ethereal vapour in the interior of the instrument. The consequent evaporation from the included ether produces a depression of temperature in the ball *b*, the degree of which is measured by the thermometer *d e*. This action is almost instantaneous, and the thermometer begins to fall in two seconds after the ether has been dropped. A depression of 30 or 40 degrees is easily produced, and the ether is sometimes observed to boil and the thermometer to be

driven below zero of Fahrenheit's scale. The artificial cold thus produced causes a condensation of the atmospheric vapour upon the ball *b*, which first makes its appearance in a thin ring of dew coincident with the surface of the ether. The degree at which this takes place must be carefully noted. In very damp or windy weather the ether should be very slowly dropped upon the ball, otherwise the descent of the thermometer will be so rapid as to render it extremely difficult to be certain of the degree. In dry weather, on the contrary, the ball requires to be well wetted more than once, to produce the requisite degree of cold. (*Daniell's Meteorological Essays.*)

The instrument which has now been described is extremely beautiful in principle; but it may be doubted whether, even when the greatest caution is observed, the temperature which it indicates is precisely that at which the deposition of dew takes place. The deposition first occurs in a narrow ring on a level with the surface of the ether in the ball *b*, thereby indicating that the ether is colder at the surface than a little under it. But if the temperature is not uniform throughout the ball, it is evident that only a small part of the bulb of the thermometer can be placed in the point where the greatest cold exists; consequently the temperature indicated by the thermometer will be greater than is necessary for producing the deposition of moisture: in other words, the dew point will be given too high.

Various attempts have been made to obviate the defects of Daniell's hygrometer, but hitherto without much success. The apparatus proposed by Pouillet may be described as follows:—A small cup C C, formed of gold, and extremely thin, is fixed to a little collar of ivory B B′ supported on a stand. The stem of an inverted thermometer T T descends through a perforation in the bottom of the cup, and is fitted closely into it and sealed, the ball of the thermometer being placed at the centre of the cup. In order to prevent the mercury from separating, a small portion of air is left in the stem. When an observation is to be made sulphuric ether is poured into the cup; and in consequence of the rapid evaporation which takes place a considerable degree of cold is produced, and a deposition takes place on the outside of the cup. The degree of the thermometer at the instant the brightness of the metal begins to be dimmed gives the dew point. The correctness of the indication depends on the identity of temperature of the ether, the metal of the cup, and the thermometer. Bright gold is found to answer the purpose better than any other metal. (Pouillet, *Élémens de Physique.*)

(2.)



As the hygrometer is one of the principal instruments in meteorological researches, its theory and the best form of its construction have been the subject of frequent discussion in the various scientific journals.

HY′GROME′TRIC. This term is commonly applied to substances which readily become moist and dry with corresponding changes in the state of the atmosphere, or which readily absorb and retain moisture. Sea weed, several saline substances, porous clays, potash and its carbonate, chloride of calcium, sulphuric acid, are in this sense of the term said to be hygrometric.

HY′GROSCOPE. (Gr. ὑγρος, and σκοπεω, *I view.*) An instrument by means of which changes in the condition of the atmosphere with respect to moisture are observed. *See* HYGROMETER, by which the same changes are measured.

HY′LÆOSAU′RUS. (Gr. ὕλη, *a wood*, and σαυρος, *a lizard.*) A name given by Dr. Mantell to an extinct gigantic genus of reptiles, the fossil remains of which he has discovered in the wealden strata of Sussex.

HYLO′BIUS. (Gr. ὕλη, and βιος, *life.*) A genus of Tetramerous Coleoptera, belonging to the *Curculionidæ*, or family of weevils, and noted for the ravages committed by one species, *Hylobius abietis* (*Curculio abietis* and *Curculio pini* of Linnæus) upon firs and larches, especially in young plantations. This insect varies from five to nine lines in length, is of a pitchy black colour, with numerous yellow spots on the elytra. It has been found in the pine woods of Shropshire, the north of England, and Scotland.

HYLOZO′ISM. (Gr. ὕλη, *wood*, used by ancient philosophers to signify the abstract idea of matter, and ζωη, *life.*) In Philosophy, strictly the doctrine that matter lives. Some writers have confined this name to the tenet of the *anima mundi*, or soul of the world; others to the theory of a peculiar life residing in the whole of nature, approaching, therefore, in its sense to pantheism. This life is either merely organic or actually sentient: the latter notion has been also called *hylopathism*. (See the remarks on Cudworth's Intellectual System in *Hallam's Literature of Europe*, iv. 188.; and *Ersch and Gruber's Encyclopædia.*)

HY′MEN. Among the ancients, the God of Marriage. The origin of the worship of this divinity is attributed to the following story:—A young Athenian, named Hymenæus, in humble circumstances, having become enamoured of a rich and noble lady, from whose presence he was debarred, attired himself in female habiliments, and joined a religious procession to Eleusis, in which his mistress took part. On their way thither the parties who composed it were attacked by pirates, who carried them into captivity; but Hymenæus seized the opportunity when they were asleep of putting them to death, and departing immediately for Athens, engaged to restore all the ladies to their families on condition of his obtaining permission to marry the object of his affection. The Athenians consented; the nuptials of Hymenæus were crowned with happiness; and from that period the Greeks instituted festivals in his honour, and invoked him at the celebration of their marriages. The formula employed on these occasions was, "O Hymenæe Hymen, Hymen O Hymenæe." (*Cat. Carm.* 61, 62.) *Hymeneal* is used to signify a song or ode composed in celebration of a marriage.

HYME′NIUM, in describing fungi, denotes that part in which the sporules immediately lie. It is commonly called the gills in the genus *Agaricus*; but in *Boletus* is a corky or spongy substance pierced full of holes, and in other genera presents a variety of peculiar appearances.

HYMENO′PTERANS, *Hymenoptera*. (Gr. ὑμην, *a membrane*, and πτερον, *a wing.*) An order of mandibulate insects, comprehending those which have four membranous wings with few nervures. Latreille divides this order into the following sections and tribes:—

1. *Terebrantia:* Abdomen of the females furnished with a saw or borer.
   - *a. Securifera:* Abdomen sessile, furnished with a saw; larvæ with feet.
   - *b. Pupivora:* Abdomen pedunculated, furnished with a borer; larvæ footless.
2. *Aculeata:* Abdomen of the females armed with a sting.
   - *a. Heterogyna:* Females wingless.
   - *b. Fossores:* Females winged, wings not folded; basal joint of posterior tarsi simple.
   - *c. Diploptera:* Females winged, wings folded.
   - *d. Mellifera:* Females winged, wings not folded; posterior tarsi enlarged, and converted into a polliniferous organ.

(See the above terms; and APIS and FORMICA.)

HYMN. (Gr. ὑμνος.) An ode in praise of the Deity, or some divine personage. The earliest Greek hymns are those attributed, probably without foundation, to Homer: imitated by Callimachus. They are in heroic verse, except one of Callimachus in hexameters and pentameters; and their contents, for the most part, are narrations of the events in the mythological history of the respective gods and goddesses to whom they are dedicated, related in an encomiastic strain. The choric strains of some of the tragedians in honour of deities, introduced into their dramas, appear also to have the character of hymns; especially as dramatic performances, among the Greeks, had something of a religious solemnity attached to them. The Theurgic Hymns were strains of a higher character, and intended only for those who were initiated into certain mysteries, supposed to have for their object the diffusion of more exalted notions of the divinity. Those which are falsely attributed to Orpheus, and pass by his name, are said to be of this class; but, except from their obscurity, it is difficult to say from what reason. Philosophical hymns, intended for the use of the followers of a still higher species of worship, are mentioned in the division of ancient hymns; but we have no genuine examples of such compositions. In modern literature, hymns are pieces of sacred poetry intended to be sung in churches; of which the Psalms of David, the most ancient pieces of poetry, properly so called, on record (except the book of Job), furnish the chief example and model. St. Hilary, bishop of Poitiers, is said to have been the first who composed hymns to be sung in churches. The Latin hymns of the Roman Catholic church are well known, from the exquisite music to which they have been united. (See *Riddle's Christian Antiquities*, p. 313. As to the classical hymns and hymnographers, see the *Mem. de l'Acad. des Inscr.* vols. xii. and xvi.)

HY′OSCYA′MIA. The active principle or alkaloid of the common henbane (*Hyoscyamus niger*).

HYPÆ′THRAL. (Gr. ὑπο, *under*, and αιθηρ, *the air.*) In Architecture, a building or temple uncovered by a roof. The temples of this class are arranged by Vitruvius under the seventh order, having six columns in front and rear, and surrounded by a *dipteral* or double portico. The famous temple of Neptune at Paestum, still remaining, is an example of this species of building.

HYPA′LLAGE. (Gr. ὑπαλλασσω, *I change slightly.*) In Grammar and Rhetoric, a species of inversion, in which not only the natural or customary succession of words is changed, but the sense presents a species of transposition, in which predicates are transferred from their proper

subject to another. Such examples as "gladium vagina vacuum," *the sword empty of the scabbard*, "in nova fert animus mutatas dicere formas corpora," where the adjective "new" is transferred from "form" to "body," present striking instances of this figure; but although such deviations from the natural sense could not be admitted in modern language, similar locutions are not wholly wanting among ourselves.

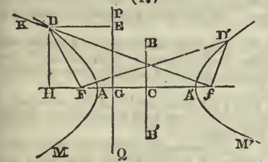
HYPANTHO'DIUM. A term given by Link to that form of inflorescence where the receptacle is fleshy and covered with minute flowers, but not enclosed within an involucrum; as in *Dorstenia* and *Ficus*.

HYPE'RBOLA. (Gr. ὑπερβολη; from ὑπερ, *above*, and βαλλω, *I throw*.) In Geometry, one of the conic sections, formed by cutting a cone by a plane which is so inclined to the axis that when produced it cuts also the opposite cone, or the cone which is the continuation of the former on the opposite side of the vertex. The term *hyperbola* was given to this curve by Apollonius on account of its property, that the square of any ordinate is greater than the rectangle under the corresponding absciss and the parameter, or differs from that rectangle in *excess*.

Like the ellipse and parabola, the hyperbola may be defined in various ways, and all its properties investigated without any reference to the cone, but considered entirely as a plane curve. The definitions most usually adopted are the following: —

If two points F and f be given in a plane, and a point D be conceived to move around them in such a manner that the difference between the two distances D F and D f is always constant the point D will describe on the plane an hyperbola D A M. By assuming first one of the given points F, and then the other f, as that to which the moving point is nearest, the difference of the lines D F and D f in both cases being the same, two hyperbolas D A M and D′ A′ M′ will be described opposite to each other; so that the curve consists of two branches.

(1.)



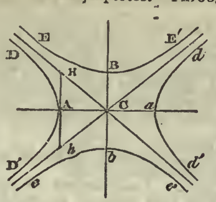
The points F and f are the *foci* of the hyperbola; and C, which bisects the distance between the foci, is its *centre*. The line A A′ is the *major* or *transverse axis*: and a straight line B B′, passing through the centre, perpendicular to A A′, and of such a length that the square of its half C B or C B′ is equal to the difference between the squares of C F and C A, is the *minor* or *conjugate* axis. The curve may be described mechanically as follows: — Let one end of a string be fastened to F, and the other to K, the extremity of a ruler f D K; and let the difference between the length of the ruler and of the string be equal to A a. Let the other end of the ruler be fixed to the point f, and let the ruler be made to revolve about f as a centre in the plane in which the axes are situated, while the string is stretched by means of a pin D, so that the part of it between K and D is applied close to the edge of the ruler: the point of the pin will by its motion trace a curve line D A M upon the plane, which is one of the hyperbolas required; and if the ruler be made to revolve about the other focus F, while the end of the string is fastened to f, the opposite hyperbola will be described by the pin D′.

2. The hyperbola may also be defined as follows: — Let F be a given point, and P Q a straight line given in position; if another point D move in the same plane, so that its distance D F from F shall have always to the perpendicular D E, or its distance from the given line P Q, the constant ratio of two given lines X and Y, of which X is greater than Y, the locus of the point D will be a hyperbola. The line P Q is called the *directrix*, and its distance C G from the centre C is such that C G is a third proportional to C F and C A. It is obvious that F A is to A G in the given ratio of X to Y.

3. Another distinguishing property of the hyperbola is that the rectangle under A H and H A′ is to the square of the ordinate H D in the ratio of the square of C A to the square of C B. Let C A $= a$, C B $= b$, C H $= x$, and H D $= y$; then A H · H A′ : H D^2 : : $a^2 : b^2$, that is, $(x - a)(x + a) : y^2 : : a^2 : b^2$, or $x^2 - a^2 : y^2 : : a^2 : b^2$; whence $y^2 = \frac{b^2}{a^2}(x^2 - a^2)$, an equation which may be put under this form, $\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1$.

4. Like the ellipse, the hyperbola may also be defined by a polar equation. Let F D $= r$, C A $= a$, C F the eccentricity $= e$, and the angle A F D $= \phi$; then $r = \frac{e^2 - a^2}{a + e \cos. \phi}$.

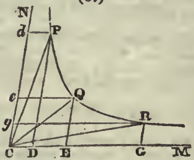
The hyperbola has two infinite branches, and it has also two asymptotes. Through A, one of the vertices of the transverse axis, let a straight line H A h be drawn equal and parallel to B b, the conjugate axis, and bisected at A; the straight lines C H, C h, drawn through the centre, and the extremities of that parallel, are asymptotes, and if produced indefinitely do not meet the curve, though their distance from it becomes less than any assignable line.



The asymptotes of two opposite hyperbolas are common to both; and they are likewise the asymptotes of two other hyperbolas, E B E′, $e\ b\ e'$, whose transverse axis B b is the conjugate axis of D A D′, and whose conjugate axis is the transverse axis of D A D′. These two hyperbolas, E B E′ and $e\ b\ e'$, are called *conjugate* to the former pair; and, in general, whatever property belongs to the opposite hyperbolas D A D′, $d\ a\ d'$, the same belongs also to the conjugate hyperbolas E B E′ and $e\ b\ e'$.

One of the most remarkable properties of the asymptotes is the following: — If one of the asymptotes C M be divided in continued proportion in the points D, E, G, &c., and straight lines be drawn from the points of section parallel to the other asymptote, meeting the curve in the points P, Q, R, &c.; the spaces D P Q E, E Q R G, &c., without the curve, are equal. The hyperbolic sections C P Q, C Q R, &c., are also equal to each other, and to the spaces D P E Q, E Q R G, &c.

(3.)



Hence, from the nature of logarithms, the sectors C P Q, C P R, &c., or the equal spaces D P Q E, D P R G, &c., represent the logarithms of the ratios of C D to C E, to C G, &c.; and if C D represent the unit of the arithmetical scale, the sector C P Q, or the space D P Q E, will express the logarithm of C E on any logarithmic system depending on the angle of the asymptotes. From the points P, Q, R, &c. let P d, Q e, R g, be drawn parallel to C M; the ordinates C d, C e, C g, &c. are also in geometrical progression decreasing; and wherever the points D, E, G, &c. are situated, all the parallelograms C d P D, C e Q E, C g R G, &c. are equal. Hence if C M be taken as the line of the abscissa, and the ordinates be taken parallel to C N, and if we make at the same time C E $= a$, C e $= b$, the nature of the curve will be expressed by this equation, $x\,y = a\,b$. *See* CONIC SECTIONS.

HYPE'RBOLE. In Rhetoric, a figure by which expressions are used signifying more than it is intended to represent to the hearer or reader; as when thoughts and sentiments are clothed in tumid language, or ideas are brought forward which in themselves are incredible, in order to induce a belief of something less than that which is offered. Exaggeration is hyperbole applied to narrative, when false assertions are added to true in order to increase the impression made by them.

HYPERBO'LIC LOGARITHMS. A system of logarithms; so called because the numbers express the areas between the asymptote and curve of the hyperbola, those areas being limited by ordinates parallel to the other asymptote, and the ordinates decreasing in geometrical progression. But as such areas may be made to denote any system of logarithms whatever, the denomination is not correct. The term Napierean logarithm (from the inventor of the logarithms, Baron Napier) is more frequently used, at least by the Continental writers, to denote the same thing. The hyperbolic logarithm of any number is to the common logarithm of the same number in the ratio of 2·30258509 to 1, or as 1 to ·43429448. *See* LOGARITHM.

HYPE'RBOLOID, or HYPERBOLIC CONOID. (Gr. ὑπερβολη, and ειδος, *form*.) A solid formed by the revolution of an hyperbola about its axis. *Hyperboloids* also denote hyperbolas of the higher kind, defined, generally, by the equation $x^m\,y^n = a^{m+n}$. The asymptotic area of any hyperbola of which this is the equation is $\frac{n}{n-m}\,x\,y$; and it is very remarkable that this space is always quadrible, except in the case of the common hyperbola, in which m and n being each 1 the denominator $n - m$ becomes zero.

HY'PERCATALE'CTIC. (Gr. ὑπερ, *above*, and καταληκτικος, *deficient*.) In Greek and Latin poetry, a verse exceeding its proper length by one syllable.

HY'PERCRI'TICISM, consists in viewing the works of an author in an ungenerous spirit, exaggerating minor defects, and overlooking or undervaluing such merits or

beauties as might fairly be considered to outweigh the former.

HY'PERICA'CEÆ. (Hypericum, one of the genera.) A natural order of Exogenous plants, usually having yellow flowers, with the petals wider on one side than the other, and marked with black dots, while the leaves are in many cases marked with transparent dots. They are usually strong-scented and astringent. Some of them have coppery red flowers, and yield a resinous substance resembling gamboge.

HYPE'RION. *See* TITAN.

HYPE'ROCHE. (Gr. *pre-eminence.*) In Music, an interval nearly equal to one comma and a half.

HYPEROXYMU'RIATES. Combinations of the chloric and perchloric acids were formerly so called: thus, chlorate of potash was called hyperoxymuriate of potash.

HY'PERSTHENE. Labrador hornblende. It is a ferrosilicate of magnesia, with traces of alumina and of lime. It occurs crystalline and massive; it is resplendent, and of a grey green or reddish hue.

HY'PERTHYRUM. (Gr. *ὑπερ*, *upon*, and *θυρα*, *a door.*) In Architecture, the lintel of a doorway.

HYPE'RTROPHY. (Gr. *ὑπερ*, and *τροφη*, *excess of nutrition.*) A term frequently applied to the morbid enlargement of any part of the body "This term ought to be restricted to cases in which a part, though increased in bulk, retains its natural organization and structure." (*Cooper's Dictionary.*)

HY'PHA, in describing *Algæ*, denotes the filamentous, fleshy, watery thallus of *Byssaceæ.*

HY'PHEN. (Gr. *ὑφεν*, *together with.*) In Writing, a mark or character thus (-), implying that two words or syllables are to be connected.

HYPNO'TICS. (Gr. *ὑπνος*, *sleep.*) Medicines which induce sleep.

HYPOCAU'STUM. (Gr. *ὑπο*, *under*, and *καιω*, *I burn.*) In Ancient Architecture, a vaulted apartment from which the fire's heat is distributed to the rooms above by means of earthen tubes. This method, first used in baths, was afterwards adopted in private houses, and diffused an agreeable and equable temperature throughout the different rooms.

HY'POCHONDRI'ASIS. (Gr. *ὑπο*, *under*, and *χονδρος*, *cartilage.*) Uneasiness about the region of the stomach and liver, or of the hypochondriac region, is one of the symptoms of this disease. Particular circumstances may induce this disorder in any individual; but it is most commonly met with in persons of sallow or pale complexions, spare habit of body, and dark hair and eyes. Its mental symptoms are low spirits, a groundless apprehension of evil, imaginary local sensations, and erroneous impressions respecting the opinions and sentiments of others, with a tendency to misconstrue their actions; aversion to society; want of mental and bodily energy; seeing persons and things and hearing conversations and noises which are purely imaginary. The bodily symptoms are flatulency and all the other concomitants of indigestion,— costiveness, dimness of sight, noises in the ears, want of appetite and sleep in most cases, in a few voracity and drowsiness. As this disease is usually connected with imperfect action of the liver and debility of the stomach and bowels, mild aperients, small doses of calomel or blue pill, and tonics are to be prescribed; occasionally doses of more powerful purges, such as calomel and jalap, or scammony with salts and senna, must be resorted to where the bowels are foul and overloaded; and where there is much headach a blister to the neck, or the loss of a *little* blood by cupping, or from the arm, may be of service. The regularity of the circulation is often much disturbed, and it is generally necessary to keep the feet warm.

Change of scene and of occupation, cheerful society, moderate exercise of all kinds, and great kindness and attention on the part of the medical adviser, are generally among the essentials in the treatment of this diseased state. But every amusement and relaxation must be carefully proposed and pursued; and though it is generally necessary firmly but gently to remonstrate against the whims and caprices of hypochondriacs, yet sometimes they must be conceded to. When persons are full of evil forebodings and false alarms, it is sometimes well to induce them to keep a diary of their feelings, the perusal of which as they recover, or in their happier moments, is often comforting proof to them of the utter want of foundation of some of their most inveterate notions. Persons who are very irritable and over-anxious, or who, after having been actively engaged in business, retire to a life of ease and idleness, who take no interest in study, amusement, or exercise; and those, again, who have kept bad hours, or who have led debauched lives, or who have studied intensely,— are those in whom some of the worst forms of hypochondriasis occur. It is seldom, in the most aggravated cases of this disorder, that well-grounded hopes of recovery may not be held out, and that its recurrence may not be prevented by timely and firm treatment; but if it be allowed to run its course, it often ends in melancholy.

HY'POCRATE'RIFORM. (Gr. *ὑπο*, *κρατηρ*, *a cup*, and *φορμη*, *shape.*) That form of a corolla which consists in a cylindrical tube which is longer than the flat spreading limb, as in the flowers of the genus *Phlox*. It is called in English salver-shaped.

HYPOGÆ'OUS. (Gr. *ὑπο*, and *γη*, *the earth.*) Literally subterranean. In Botany it denotes all parts in plants which grow beneath the surface of the earth.

HY'POGENE. (Gr. *ὑπο*, and *γινομαι*, *I am formed.*) A class of rocks which have not assumed their present form and structure at the surface of the earth, but are apparently of igneous origin, and thrust up from below. *See* GEOLOGY.

HYPO'GYNOUS (Gr. *ὑπο*, and *γυνη*, *a female*), in Botany, in describing the situation of plants denotes any thing growing from below the base of the ovarium.

HY'POMO'CHLION (Gr. *ὑπο*, and *μοχλος*, *lever*), in Mechanics, is the fulcrum or support of a lever, or the point against which the pressure is exerted. This term is only met with in the old treatises on mechanics; the equivalent term fulcrum being now generally used.

HY'PONI'TROUS ACID. An acid intermediate between nitric oxide and nitrous acid, composed of 1 equivalent of nitrogen = 14, and 3 of oxygen = 24, the equivalent of the hyponitrous acid, upon the hydrogen scale, being = 38.

HY'POPHO'SPHOROUS ACID. An acid composed of 2 atoms of phosphorus and 1 of oxygen, or 32 phosphorus + 8 oxygen.

HYPOPHY'LLIUM. (Gr. *ὑπο*, and *φυλλον*, *a leaf.*) A term invented to denote a petiole that has the form of a small sheath, is destitute of lamina, and surrounds the base of certain small branches, having the appearance of leaves; as in asparagus. It is nothing but a rudimentary leaf.

HYPO'PIUM. (Gr. *ὑπο*, and *πυον*, *pus.*) A disease of the eye, in which there is an apparent collection of pus under the transparent cornea; that is, in the chamber of the aqueous humour.

HYPOSCE'NIUM. (Gr. *ὑπο*, and *σκηνη*, *a scene.*) In ancient Architecture, the front wall of a theatre facing the orchestra from the stage.

HYPO'STASIS. (Gr. *ὑποστασις*, from *ὑπο* and *ἱστημι*, *I stand.*) A term invented by the Greek fathers to express the distinct *personality* of the Father, Son, and Holy Ghost. *Προσωπον*, in Latin persona, whence our *person*, signifies properly a face or mask. This term, however, is retained by the Latin fathers, who, like ourselves, had no word which could exactly represent hypostasis, which differs from *οὐσία*, *substance*, inasmuch as the latter is used for the divine substance, essence, or being,— that which is common to each of the hypostases, persons, or individual substances which compose the one Godhead.

HY'POSULPHU'RIC ACID. An acid intermediate between the sulphurous and sulphuric acids. It may be regarded as containing 2 atoms of sulphur ($16 \times 2 = 32$), and 5 of oxygen ($8 \times 5 = 40$); or as constituted of 1 atom of sulphurous acid = 32, and 1 of sulphuric acid = 40. In either case its equivalent is 72.

HYPOSULPHU'ROUS ACID. An acid constituted of 2 atoms of sulphur ($16 \times 2 = 32$), and 2 of oxygen ($8 \times 2 = 16$). It is necessary to take this view of composition, its equivalent number being 48.

HYPO'THECA'TION. (Gr. *ὑποθηκη*, *that which is subject to a pledge.*) In the Civil Law, an engagement by which the debtor assigns his goods in pledge to a creditor as a security for his debt, without parting with the immediate possession; differing, in this last particular, from the simple pledge. The term hypothecation is usually applied to things immoveable only (*i. e.* according to the division of the English law, to things real, things personal savouring of the realty, and choses in action), and not to things moveable (*i. e.* things personal in possession). It answers in general to the English mortgage. *See* MORTGAGE.

HYPO'THENUSE (Gr. *ὑπο*, and *τεινω*, *I stretch*), in Geometry, denotes the longest side of a right-angled triangle, or the side which subtends the right angle. The famous 47th proposition of the First Book of *Euclid*, namely, that in any right-angled rectilinear triangle the square described on the hypothenuse is equal to the sum of the squares described on the two sides, is said to have been discovered by Pythagoras, who was so much pleased with it that he sacrificed a hecatomb to the Muses in gratitude. Camerer, in the Notes to his edition of the first Six Books of *Euclid*, in Greek and Latin, has collected no fewer than seventeen different demonstrations of this celebrated theorem from the principles of elementary geometry.

HYPO'THESIS (Gr. *ὑποθεσις*, from *ὑπο*, and *τιθημι*, *I place*), in Mathematical Science, is a supposition made with a view to draw from it some consequence which establishes the truth or falsehood of a proposition, or gives the solution of a problem. In a mathematical proposition there are two things to be considered,— the *hypothesis* and the *conclusion;* the hypothesis being that which is granted or supposed, and the conclusion that which follows from

reasoning from the data. In the following proposition, "If two triangles be equiangular, their homologous sides are proportional;" the first part, *if two triangles be equiangular*, is the hypothesis or *data* from which we are to reason; and the second part, the *homologous sides are proportional*, is the conclusion or consequence at which we arrive by reasoning from that hypothesis.

In Physics, the term hypothesis denotes a gratuitous supposition to account for some phenomenon or appearance of the natural world. If the hypothesis serves to explain a great number of the circumstances accompanying a phenomenon, it acquires a certain degree of probability; and if all the known circumstances can be deduced from it, the probability becomes very great, and in the lapse of time may amount to certainty. Thus the hypothesis of the diurnal rotation of the earth and its translation in the ecliptic, imagined by Copernicus to explain the planetary phenomena, has acquired all the characters of certainty from continual astronomical observation. In like manner, Kepler's hypothesis that the planets move in elliptic orbits, has been so fully confirmed by subsequent discoveries and computations, that, however doubtful it might be at first, no one who is capable of understanding the evidence can hesitate to receive it as an established law of nature. "A well-imagined hypothesis," says Sir John Herschel, "if it have been suggested by a fair inductive consideration of general laws, can hardly fail at least of enabling us to generalize a step further, and group together several such laws under a more universal expression. But this is taking a very limited view of the value and importance of hypotheses. It may happen (and it has happened in the case of the undulatory theory of light) that such a weight of analogy and probability may be accumulated on the side of an hypothesis, that we are compelled to admit one of two things — either that it is an actual statement of what really passes in nature; or that the reality, whatever it be, must run so close a parallel with it as to admit some mode of expression common to both, at least in so far as the phenomena actually known are concerned. Now, this is a very great step, not only for its own sake, as leading us to a high point in mathematical speculation, but for its applications because whatever conclusions we deduce from an hypothesis so supported must have at least a strong presumption in their favour; and we may be thus led to the trial of many curious experiments, and to the imagining of many useful and important contrivances, which we would never otherwise have thought of, and which, at all events, if verified in practice, are real additions to our stock of knowledge and to the arts of life." (*Discourse on the Study of Nat. Philosophy*.)

HY'POTRACHE'LIUM. (Greek ὑπο, *under*, and τραχηλος, *the neck*.) In Architecture, the slenderest part of the shaft of a column, being that immediately below the neck of the capital.

HY'POTYPO'SIS (Gr. ὑποτυπωσις, from τυπος, *a type*), in Rhetoric, signifies an animated representation of a scene or event in descriptive language highly enriched with rhetorical figures.

HY'RAX. (Gr. ὑραξ, *a shrew-mouse*.) This term is now applied to a genus of small Mammalia which rank next the rhinoceros in the order of their affinities, and are the most diminutive representatives of the Pachydermatous order. The two known species are found in hilly districts at the Cape (*Hyrax capensis*), and in Syria (*Hyrax Syriacus*): the latter species is the "coney" of Scripture.

HYSTERA'NTHUS, in describing the duration of leaves. denotes their appearance after the flowers; as in the almond.

HYSTE'RIA. (Gr. ὑστερα, *the womb*, with which it is supposed that the disease is generally connected.) It generally attacks unmarried females between the ages of 15 and 35, coming on with low spirits and anxiety, sickness, short breath, and palpitations; sobbing; and a sense of distension of the bowels, which afterwards seems to concentre itself in the stomach, and then rise like a ball into the throat, where it produces gasping, stupor, convulsive motions, crying, laughing, hiccough, flow of saliva from the mouth, and delirium: at length the spasms abate, and the person gradually recovers, generally with the expulsion of wind from the stomach. Some of these symptoms are often much more prevalent than others, so that the disorder assumes many forms: it is also very variable in its duration, lasting from an hour or two to one or two days. The treatment varies extremely with the apparent causes of the disorder; sometimes bleeding and depletives, at others stimulants and tonics are required; in mild cases sprinkling with water and applying nasal stimulants give relief. Great attention to the exciting cause, exercise, moderate and judicious amusements and occupations, regular hours, and change of air and scene, are among the best preventives of its recurrence.

HYSTERI'TIS. Inflammation of the womb. This dangerous disease generally occurs the second or third day after delivery; it is attended by fever and pain of the part, and requires active antiphlogistic treatment.

HYSTERO'LOGY, or HYSTERON PROTERON. (Gr. ὑστερος, *the latter of two*, and λογος, *speech*.) In Rhetoric, a figure by which the ordinary course of thought is inverted in expression, and the last put first; as, where objects subsequent in order of time are presented before their antecedents, cause before effect, &c. Some comprehend the figure usually called anticlimax (*see* CLIMAX) under the name Hysterology.

HY'STRICI'DÆ. (Gr. ὑστριξ, *a porcupine*.) The name of the family of Rodent Quadrupeds, of which the porcupine (*Hystrix cristata*) is the type.

I AND J.

I, the ninth letter of the English and most European alphabets, represents two very different sounds in different languages. In England it is equivalent to the French or German sounds of the two letters *a i*, pronounced rapidly; and in the German and all other languages with which we are acquainted, it is identical with the sound of the long English *e*. In the Greek language the letter *i* is the simplest of the alphabetical characters, being represented by a single stroke, thus, ι. It is also susceptible of various interchanges, more particularly in the Latin, Greek, and French languages. When two *i*'s followed in succession, the Romans used to contract them into a single long *i*, as *Di* for *Dii*, *tibicen* for *tibiicen*; or made the letter larger than usual, as *ChIus*. Shakspeare sometimes substitutes *I* for ay or yes.

> Did your letters pierce the queen?
> *I*, sir; she took 'em and read 'em in my presence.

According to Gebelin, the letter *i* in hieroglyphic writing represents the human hand, the instrument of which man avails himself in all his necessities, the seat of his power and might. As a Roman numeral it denotes 1; and if placed before V or X, it diminishes by a unit the number expressed by these two letters. The form of J was originally identical with that of I; and it is only within the last century that any distinction was made between them. In the English and French languages J has a sibilant sound, but the Germans pronounce it exactly as the English *y* before a vowel. The Latin sound of this letter is very ambiguous, the question being usually decided by the parties who discuss it according to its pronunciation in the vernacular. In the Spanish language J represents a guttural, and is frequently substituted for X, which has the same sound.

IA'CCHUS. *See* BACCHUS.

IA'MBICS. A species of verse used by the Greek and Latin poets, and especially by the Greek tragic poets. The derivation of the word has never been ascertained, but it can boast of an origin nearly coeval with the Greek language. The iambics of the Greek tragic poets consisted of three entire metres or six feet, and were thence styled the tragic *trimeter acatalectic*. They were composed originally, as their name implies, of a succession of iambi (◡ –); but at a later period, various other feet were admitted, of which the subjoined table will convey an idea.

1.	2.	3.	4.	5.	6.
◡ –	◡ –	◡ –	◡ –	◡ –	◡ –
◡ ◡ ◡	◡ ◡ ◡	◡ ◡ ◡	◡ ◡ ◡	◡ ◡ ◡	
– –		– –		– –	
– ◡ ◡		– ◡ ◡			
◡ ◡ –					

Hence it will be seen that a tribrachys may be introduced into all the places except the last; a spondee in the first, third, and fifth places: a dactyl in the first and third places; and an anapest in the first. It was, however, long a question of great doubt among grammarians into what places the anapest might be legitimately introduced. The discussion at one period ran high, particularly between English and German critics; but it now seems to be universally admitted that this foot may be used in every odd place of the verse except the last: with the general restriction, that in the 3d and 5th places it should be contained in a proper name, as Antĭgŏnē, or in a preposition and the word which it governs. The comic writers used much greater licence in the iambic trimeter, admitting an anapest, even in common words, into every place but the last. For a full exposition of this and the other iambic metres employed by the Greek and Latin poets, the reader may consult *Hermann's Elementa Doctrinæ Metricæ; Porson's* editions of the *Tragedies of Euripides;* and the article "Iambic Verse" in *Rees's Cyclopædia*. In most modern European languages, the verse of five iambic feet is a favourite metre. In French it is used almost entirely in lighter poetry, as by La Fontaine and similar writers, the heroic verse being the sixth foot, or alexandrine; but in English, German, and Italian, the former is the verse of ordinary use in serious composition. The Italians divide it into — 1. The *verso cadente*, in which the line is decasyllabic, consisting of five iambi: *e.g.*

> "E come albero in nave si levo." DANTE.

This variety is very rarely admitted in serious composition, and is ill suited to the character of the language. Poets have, however, sometimes sportively attempted whole series of versi cadenti; as in the set of sonnets of Casti, called *I tre Giuli*. 2. The verso eroico, or hendecasyllabic, which is the ordinary one, ending in a short syllable:

"Canto l'armi pietose, e 'l capĭtānŏ."

3. The verso sdrucciolo, which ends with two short syllables after the fifth iamb:

"Passi oziosa, e di tua gloria immēmŏrĕ."

This also is rarely used in serious writing; but its occasional employment adds a peculiar grace to lighter poetry. In English, according to the genius of the language, the decasyllabic line is most common; the hendecasyllabic occasional, and more frequent in blank verse than in rhymes, in consequence of the comparative rarity of trochaic rhymes; the sdrucciolo, also occasionally used by dramatic poets: *e. g.*

"What's Hecuba to him, or he to Hēcŭbă?"

The licence is sometimes carried so far as to add three short syllables to the last iamb: *e. g.*

"The senator shall bear contempt herēdĭtărȳ."

The German language is rich both in iambic and trochaic terminations: consequently the decasyllabic and hendecasyllabic are more indiscriminately employed than in either English or Italian; and it is not uncommon to use the elegant variety of alternate iambic and trochaic rhymes, like the French masculine and feminine.

I'BEX. (Lat. *a wild goat.*) The name is restricted to a species of goat; the *Capra ibex* of Linnæus, *Bouquetin* of Buffon and the French naturalists. It is characterized by having large horns, with a flattened anterior surface, and marked with prominent transverse ridges or knots. It inhabits the summits of the highest mountain chains in the continents of Europe, Africa, and Asia, but does not exist in the New World.

I'CEBERG. (Germ. eis, *ice*, and berg, *mountain.*) The name given to the masses of ice resembling mountains often found floating in the polar seas. They are sometimes formed in the sea itself by the accumulation of ice and snow; at other times they seem to be glaciers which have been piling up on shore till quite overgrown, and ultimately broken and launched into the ocean by their own weight. Masses of this sort abound in Baffin's Bay, where they are sometimes two miles long, and half or one third as broad. Scoresby counted 500 of these bergs drifting along in latitudes 69° and 70° N., which rose above the surface from the height of 100 to 200 feet, and measured from a few yards to a mile in circumference. (*Voyage in* 1822, p. 233.) Many of them were loaded with beds of earth and rocks, of such thickness that the weight was conjectured to be from 50,000 to 100,000 tons; and on closer examination the mass was found to be composed, among other substances, of granite, gneiss, micaschist, clayslate, granular felspar, and greenstone. Some idea may be formed of the immense depth to which icebergs descend, from the fact that the mass of ice below the level of the water is about eight times greater than that above. Icebergs have been known to drift from Baffin's Bay to the Azores, and from the South Pole to the immediate neighbourhood of the Cape of Good Hope. (See *Lyell's Geology*, book ii. c. 3.; *Murray's Encyc. of Geography.*)

ICELAND MOSS, *Lichen Islandicus*, *Cetraria Islandica*. This is a common lichen in the mountainous districts of Europe. It contains a bitter principle, and a considerable quantity of starchy matter; it is tonic and nutritive, and is often prescribed in disorders of debility, and in pulmonary consumption.

ICELAND SPAR. A transparent rhomboidal variety of calcspar, or carbonate of lime. This form of crystallized carbonate of lime is particularly valuable for experiments on the double refraction and polarization of light.

ICE SPAR. A variety of felspar, from Somma near Naples.

ICH DIEN. (Germ.) Literally *I serve;* the motto of the Prince of Wales, which was originally adopted by Edward the Black Prince in proof of his subjection to his father Edward III., and has been continued without interruption down to the present time.

ICHNEU'MON. (Gr. ἰχνεύμων, Pharaoh's rat, the destroyer of crocodiles; perhaps from ιχνεύω, because it tracked the foot-prints of the crocodile.) A name applied in zoology, in a double sense, to a Viverrine genus of quadrupeds, and to a family of Pupivorous Hymenoptera. As regards the Mammalia the name is changed for *Herpestes* by Illiger, and the latter has been generally adopted by English zoologists. (*See* Herpestes for the generic characters.) The ichneumon of the Nile (*Herpestes Pharaonis*) was one of the sacred animals of the ancient Egyptians; and although many fabulous feats were narrated of it as the enemy of the crocodile, there is no doubt but that its industrious instinctive searching out of the eggs of the crocodile as an article of food tends materially to diminish the number of that destructive reptile. The ichneumon preys, however, on the eggs and young of various species of animals. Mr. Bennett relates that on one occasion a grey ichneumon (*Herpestes griseus*) killed no fewer than a dozen full-grown rats, which were loosed to it in a room sixteen feet square, in less than a minute and a half. For an account of the insect ichneumons, see Pupivora.

ICHNO'GRAPHY. (Gr. ιχνος, *a model*, and γραφω, *I draw.*) In Architecture, the representation of the ground plot of a building. In perspective it is its representation intersected by a horizontal plane at its base or ground floor.

I'CHOR. (Gr.) A thin watery discharge. By the Greeks it was applied to the divine fluid that issued from the wounds of the gods.

I'CHTHIOCO'LLA. (Gr. ιχθυς, *a fish*, and κολλα, *glue.*) *See* Isinglass.

ICHTHYO'LOGY. (Gr. ιχθυς, and λογος, *a discourse.*) The science which treats of the nature, uses, and classification of fishes.

Fishes are those oviparous vertebrate animals which have a heart consisting of one auricle and one ventricle, which breathe water, and have the nasal cavity communicating with the external surface only. In a few species an air-bladder is present, and so organized as to act the part of a lung; but the principal if not exclusive organ of respiration consists, throughout the whole class, of branchiæ or gills. The gills are composed of rows of slender flattened processes suspended by arches, attached in general to the hyoid bone, and covered with a membrane or tissue of innumerable minute and close-set blood-vessels. The water which the fish takes in by the mouth, instead of being swallowed, passes through the interspaces of the gills, and escapes by the fissures on each side of the head, called gill-apertures. The air contained in the water acts upon the blood, which is minutely subdivided in the branchial vessels; and the bilocular heart serves exclusively to propel the whole of the venous blood to the branchial arteries, and is thus analogous in function to the pulmonary auricle and ventricle of the warm-blooded classes. The blood having been decarbonized in the gills is collected into the dorsal arterial trunk or aorta, and is propelled, without the influence of a systemic heart, to all parts of the body; whence it is again returned by the veins to the branchial auricle and ventricle.

The whole structure of a fish is as evidently adapted for swimming as that of a bird for flight. Being suspended in a fluid of nearly the same specific gravity as itself, it needs not widely-expanded wings for its support. Many species, moreover, have the air-bladder so organized and developed as, by its contractions and dilatations, to vary the specific gravity of the fish, and aid in its ascent to the surface, or descent into the depths of the water. Ordinary progression is effected by the motions of the tail, which, by the action of powerful muscles, displaces the water alternately to the right and left; the gills, also, in expelling the water backwards, may contribute, by the reaction of the current, to propel the fish forward. The ordinary extremities, therefore, being of little use, are reduced to a low or rudimental condition; they are chiefly remarkable for the number of parts corresponding to the digital phalanges of the higher classes, and which, from their disposition, are called "rays." The pieces analogous to the bones of the arms and legs are extremely shortened, and often quite concealed; the membrane supported by the diverging rays rudely represents the hands and feet. The members thus constructed are called "fins;" those which answer to the anterior extremities are called the "pectoral fins;" those which answer to the posterior extremities are the "ventral fins." Other rays attached to peculiar bones above or between the extremities of the spinous processes support the vertical fins, which are mesial and single, either above the back, beneath the tail, or at the extremity of the tail. The upper vertical fin or fins are called the *dorsal*, the lower ones the *anal*, and the terminal one the *caudal* fin. The fin-rays are of two kinds. Some consist of a single bony piece, usually hard and pointed, sometimes flexible and elastic, and divided longitudinally; they are called "bony or spinous rays:" the others are composed of a vast number of little joints, generally branched at the extremity; they are called "soft, jointed, or branched rays." In general the fins, which are placed in pairs, and correspond to the ordinary extremities, are four in number; but sometimes there are but two, and sometimes they are entirely wanting. When both pectoral and ventral fins are present, they may have the ordinary relative position; *i. e.* the pectoral fins may be considerably in advance of the ventrals—such fishes are said to be "abdominal;" or the ventrals may be placed below, or on the same or nearly the same transverse line as the pectorals — such fishes are termed "thoracic;" or the ventrals may be situated in advance of the pectorals, under the throat of the fish — when the species are called "jugu-

lar" fishes. The vertebræ of fishes, when completely ossified, are united, with very few exceptions, by opposite concave surfaces. Most fishes have the body covered with scales. They are destitute of organs of prehension, except the teeth. The imperfection of the organ of touch is remedied in some by the development of soft tentacles or feelers.

The teeth are very various as to their number, form, and relative size. They are either anchylosed to the jaw-bones, attached to ligaments, or implanted in sockets; when the latter, the tooth has always a single and simple fang. The teeth may be placed on the maxillary, intermaxillary, or lower jaw-bones; upon the vomer or sphenoid bones; upon the palatine or pterygoid bones, the tongue, the branchial arches, or the pharyngeal plates; or they may be entirely wanting.

Besides the branchial arches, the hyoid bone supports on each side a number of rays, which support the branchial or opercular membrane. This membrane is also generally further strengthened by three osseous plates called the "opercular," "subopercular," and "interopercular" bones: the kind of door thus formed is joined to the tympanic bone, and plays upon a piece called the "preopercular" bone.

With respect to the subdivision of the class of fishes into orders, Cuvier admits the great difficulty which exists in defining them by fixed and easily appreciable characters, and after many attempts adopted the following classification.

He first divided the class into two sub-classes.

Sub-class I. *Pisces ossei*, or fishes properly so called.
II. *Pisces cartilaginei*, or *Chondropterygians*, cartilaginous fishes.

The first sub-class are arranged according to the modifications of their organs of locomotion. All the osseous fishes which have the anterior part of the dorsal fin, or the first dorsal where there are two, supported by bony rays, with some bony rays in the anal fin, and at least one bony ray in each of the ventrals, are collected into an order, called *Acanthopterygians*.

All those osseous fishes in which, with the exception of the anterior dorsal and pectoral rays, all the others are soft, constitute the order *Malacopterygians*.

The *Malacopterygii* are subdivided, according to the relative position or absence of the ventral fins, into "abdominal," "jugular," or "sub-brachial," and "apodal" fishes.

Those fishes which have the branchiæ in the form of tufts constitute the order of *Lophobranchii*.

Those fishes in which the maxillary and palatine arches are firmly united, or, as it were, soldered to the cranium, are called the *Plectognathi*.

The *Chondropterygian* fishes are divided into the three orders of—
Sturionians,
Selacians, and
Cyclostomes. (See those words.)

The chief modification in the arrangement of the class of fishes has been the consequence of a study of the nature and affinities of the numerous extinct forms, and a comparison of these with existing species.

M. Agassiz has proved that certain species, which stand out as exceptions to the ordinary form and structure of the class among recent fishes, are the types of extensive orders which peopled the seas of the ancient world, and now characterize particular strata. This naturalist has likewise observed more closely than his predecessors the relations which subsist between the external scales and the internal structure; and he accordingly proposes to arrange the class of fishes according to the modifications of the scaly covering, and divides them into four orders, each of which contains fishes having a cartilaginous skeleton: and in each there are both Acanthopterygian and Malacopterygian, Abdominal and Apodal genera. These orders are named *Placoides*, *Ganoides*, *Ctenoides*, and *Cycloides*. (See those terms.)

I'CHTHYOPHTHA'LMITE. (Gr. *ιχθυς*, and *οφθαλμος*, *the eye*.) A species of zeolite of a peculiar pearly lustre, resembling the eye of a fish (whence its name).

I'CHTHYOSAU'RUS. (Gr. *ιχθυς*, *a fish*, and *σαυρος*, *a lizard*.) A genus of extinct marine animals, which combined the characters of saurian reptiles and of fishes with some of the peculiarities of the Cetaceous Mammalia. The vertebræ of the back-bone of the *Ichthyosauri* resemble those of fishes in having their bodies joined by opposite concave surfaces; but the superior arches remain permanently detached, as in reptiles. The cranium resembles in structure that of the crocodiles, but is characterized by a peculiarly large orbit, in which a circular series of osseous sclerotic plates, analogous to those of the crocodile and birds, but relatively much larger, has been so frequently found as to prove it to be a generic structure. The nostrils are situated, not as in the crocodile, near the point of the snout, but close to the anterior part of the orbit.

The teeth resemble in structure those of the crocodiles; but are lodged, as in some of the Lacertine Sauria, in a groove, and not in distinct sockets. The locomotive extremities are similar in construction to the paddles of the whale; but they are four instead of two in number, and the anterior paddles are connected by a broad coracoid, a complete clavicle, and a supplementary coracoid bone to a strong sternum; the flattened phalangeal bones supporting the fin are polygonal, and are relatively shorter and more numerous than in the whale tribe. The hind paddles are smaller than the fore, and are attached to a pelvis similar to that of the crocodile. Small supplemental bones are wedged into the lower part of the joint of the atlas and occiput, and a few of the succeeding vertebral joints; and the tail often presents a fracture at a particular point, whence the existence of a caudal fin has been inferred. From the form and position of masses of crushed and apparently half-digested fish bones and scales in the abdominal cavity of the ichthyosaurus, it is concluded that they preyed chiefly on fish; that they had a simple and capacious stomach, and an intestine provided with a spiral valve. The geological range of the ichthyosaurus seems, says Dr. Buckland, to have begun with the muschelchalk, and to have extended through the whole of the oolitic period into the cretaceous formation. The most recent stratum in which any remains of this genus have yet been found is the chalk marl at Dover. The chief depository of the bones of the *Ichthyosauri* occurs in the lias at Lyme Regis in Dorsetshire.

ICHTHYO'SIS. (Gr. *ιχθυς*.) A roughness and thickening of the skin, portions of which become hard and scaly, and occasionally corneous, with a tendency to excrescences. Friction, warm bath, and occasionally stimulating ointments, have been of service in mitigating the progress of this disease; but it seldom yields permanently to any plan of treatment.

I'CHTHYS. (Gr. *a fish*.) A word found on many seals, rings, urns, tombstones, &c., belonging to the early times of Christianity, and supposed to have a mystical meaning, from each character forming an initial letter of the words *Ιησους Χριστος, Θεου Υιος, Σωτηρ*; *i. e.* Jesus Christ, the Son of God, the Saviour. This interpretation is not unlikely, when we consider at once the universal reverence with which the fish was symbolically regarded among most ancient nations, and the many signs and ceremonies adopted by the Christians with some change of meaning from the religious rites of the surrounding nations.

ICO'NOCLASTS. (Gr. *εικων*, *an image*, and *κλαω*, *I break*.) Literally, breakers of images; a title applied to two of the Byzantine emperors, Leo the Isaurian and his son Constantine Capronymus, who during their reigns, which extended from 726 to 795, persevered in overthrowing the images in the Christian churches, and in extirpating their worship. The 338 bishops, also, who attended a council at Constantinople in the reign of the latter prince, and declared themselves in favour of his views, were stigmatized by the orthodox party under the same name. In the year 787, however, a general council was assembled at Nicæa by the empress Irene, who inclined towards the old superstition, and the images were on this occasion restored to their former honours. This council, the second of Nice, is the last respecting which the Greek and Latin churches coincide; the practice, however, of the Greek church makes a distinction between the use of pictures, which it allows, and graven images, which it studiously rejects. (*Mosheim, Eccl. Hist.* vol. i. p. 262., transl.; *Schlosser's History of the Iconoclast Emperors*, Frankfort, 1812; *Neander*, parts 3 and 4.)

I'COSAE'DRON. (Gr. *εικοσι*, *twenty*, and *ἕδρα*, *base*.) One of the five regular or Platonic bodies, bounded by twenty equilateral and equal triangles. It may be regarded as formed of twenty equal and similar triangular pyramids, whose vertices all meet in the same point; and hence the content of one of these pyramids multiplied by twenty gives the whole content of the icosaedron. Let the linear edge of one of its faces be denoted by a; then the surface of the icosaedron is $= 5\,a^2\sqrt{3} = 8{\cdot}660254\,a^2$; and the solidity $= \frac{5}{6}\,a^3\sqrt{\frac{7+3\sqrt{5}}{2}} = 2{\cdot}181695\,a^3$. (See *Hutton's Mensuration*, or *Sharpe's Geometry Improved*.)

I'COSA'NDROUS. (Gr. *εικοσι*, and *ανηρ*, *a male*.) Literally, any flower having twenty stamens or thereabouts; but it is usually confined to those flowers in which these stamens are inserted into the calyx.

I'CTERUS. (Gr. *ικτερος*.) The jaundice: so called from its resemblance to the golden thrush, which the Latin form of the word signifies.

I'CTIDES. (Gr. *ικτις*, *a weasel*, and *ειδος*, *form*.) A genus of nocturnal carnivorous Mammals, intermediate between the Plantigrade and Viverrine Digitigrade tribes, having the plantigrade walk of the raccoons and coatis, and the slender conical snout of the civets and other *Viverridæ*. The dental formula of the genus is

$$\text{Incis. } \frac{6}{6};\ \text{can. } \frac{1.\,1.}{1.\,1.};\ \text{præmol. } \frac{3.\,3.}{2.\,2.};\ \text{mol. } \frac{3.\,3.}{3.\,3.} = 38.$$

The teeth resemble those of the *Paradoxurus*, but are thicker and more tuberculous; and thus contribute,

with the plantigrade structure of the feet, to indicate the affinity of the *Ictides* to the Plantigrade *Feræ*. Three species of the present genus are recorded; they are all natives of Southern Asia, and are called *Benturongs*. The common Indian species (*Ictides albifrons*) is of the size of a domestic cat; but its body is longer and heavier, its legs shorter, and its gait lower and more crouching. The tail is extremely thick at its commencement, and gradually tapers to its extremity, where it curls upwards. The pupil of the eye contracts during daylight into a vertical fissure. A benturong, which was kept in captivity many years, was fed on a mixed diet of animal and vegetable substances; and they most probably subsist on similar food in a state of nature.

IDE'A. (Gr. ιδεα, from ιδειν, *to see.*) Literally, the image or resemblance of any object conceived by the mind. There is no word in any language the definition of which, from the obscurity of metaphysical writers, is attended with such difficulty as the term *idea;* and the difficulty is enhanced when we consider the vagueness with which its equivalents are expressed in different languages, and the many metaphysical systems that have been constructed on their several significations. Like many other terms of mental philosophy, the word *idea* is derived from the most eminent of the senses, that of sight, and in its most extended acceptation is employed to indicate "every representation of outward objects through the senses, and whatever is the object of thought." To give even a cursory glance at the various theories of the origin and nature of ideas would be to write the history of mental philosophy from Plato to Kant, and would far exceed our limits, even if the difficulty of the subject did not deter us from the attempt. The reader will find the best exposition of some of the theories alluded to in *Dugald Stewart's Phil. Essays*, Appendix II.; *Kant's Critik der reinen Vernunft; Ritter's Geschichte der Philosophie; Reid on the Human Mind;* and the *Edin. Review, Green's Hunterian Oration*, 1840.

IDEAL (BEAU), or IDEAL BEAUTY. An expression in the Fine Arts, used to denote a selection for a particular object of the finest parts from different subjects, united in that one so as to form a more perfect whole than nature usually exhibits in a single specimen of the species; or, in other words, the divesting nature of accident in the representation of an individual. From the nature of the expression and its definition, it is clear that it more immediately attaches to the arts of painting and sculpture: in architecture it is susceptible of refinements dependent on the selection of examples, upon which, however, a less universal agreement exists.

IDE'ALISM. (Gr. ιδεα, *form.*) A term applied to several metaphysical systems, varying in its signification according to the meaning attached in each particular scheme to the word *idea;* from which it is derived. In England the best known system of idealism is that of Berkeley. In reference to this philosopher's doctrines, the word is used in its empirical sense for the object of consciousness in sensation. (*See* PERCEPTION.) In its Platonic or transcendental sense, the term *idealism* has been applied to the doctrines of Kant and Schelling; neither of whom is an idealist in the way in which Berkeley may be so called. The system of Berkeley may be thus expressed:—The qualities of supposed objects cannot be perceived distinct from the mind that perceives them; and these qualities, it will be allowed, are all that we can know of such objects. If, therefore, there were external bodies, it is impossible we should ever know it; and if there were not, we should have exactly the same reason for believing there were as we have now. All, therefore, which really exists is spirit, or the thinking principle,—ourselves, our fellow men, and God. What we call ideas are presented to us by God in a certain order of succession, which order of successive presentation is what we mean by the laws of nature.

IDE'NTITY, PERSONAL, denotes the sameness of the conscious subject, *I*, throughout all the various states of which it is the subject. The question, Wherein consists our identity, and what is its evidence? has been a source of manifold controversy to modern metaphysicians. By philosophers of the materialist school the doctrine has been ejected, as incompatible with daily and obvious experience. But independently of any hypothesis respecting the nature of the soul in itself, it has been argued, and with some plausibility, that as all our knowledge of a substance is derived from the qualities or phenomena which it presents to our senses, so that all we can mean by a substance being the same with itself is that it possesses the same qualities which it previously did (for if not, the substance is changed); so all we can know of the substance *mind* in particular is derived from observation of the changes which it undergoes. But we find that what we conceive to be the same individual does, at different periods, assume under the same circumstances widely varying appearances. A man shall laugh at what when he was a child would have excited his anger or jealousy. This reasoning contains an evident fallacy. It does, in fact, like all other reasoning of the same kind, imply that very doctrine which it means to refute. Consciousness, it is asserted, is the joint effect of two substances acting one on the other. How, then, can we affirm that one of these substances is changed, unless by assuming that the other remains the same? How can we show that the phenomenon laughter in the man is different from the phenomenon jealousy or anger in the boy, unless we admit that we who *observe* these phenomena,—*i. e.* by the premises, on whom these phenomena produce a given effect—remain the same as we were when we were affected previously in a different manner. A lump of sugar, as we take it to be, no longer melts in what we take to be water. Assuming that the water remains water, we may fairly infer that the lump in question is not sugar, or vice versâ; not so if we profess ourselves equally ignorant of the identity of both substances. This argument, it will be seen, applies equally to the materialist and non-materialist. Such may be said to be the *negative* evidence of our identity. Its positive evidence rests on the necessity and universality of its belief, as implied in every act of memory. *To remember* is to refer a past state of consciousness to the same subject which now at the present moment recals it. (See *Bishop Butler's Treatise on Personal Identity; Brown's Phil. of Human Mind.* Lect. 12, 13, 14. &c. &c.)

IDE'NTITY, SYSTEM OF. In Philosophy (otherwise called Identism), a name which has been given to the metaphysical theory of the German writer Schelling. It rests on the principle that the two elements of thought, the objects respectively of understanding and reason, called by the various terms of matter and spirit, objective and subjective, real and ideal, &c., are only relatively opposed to one another as different forms of the one *absolute* or *infinite;* hence sometimes called the two *poles* of the absolute. *See* SCHELLING, PHILOSOPHY OF.

IDEOGRA'PHIC CHARACTERS. (Gr. ιδεα, *an idea*, and γραφω, *I write.*) In Philology, characters used in writing which express figures or notions, instead of the arbitrary signs of the alphabet. The Chinese characters are ideographic, although the symbols, at first intended to represent distinct objects, have become by use merely conventional. The hieroglyphical characters of the ancient Egyptians were of the same description. Ideographical writing is opposed to phonetic. *See* PHONETIC.

IDEO'LOGY (Gr. ιδεα, and λογος, *a discourse*), literally the science of mind, is the term applied by the later disciples of Condillac to the history and evolutions of human ideas, considered as so many successive modes of certain original or transformed sensations. The writings of this school are characterized by an unrivalled simplicity, boldness, and subtlety; and the different phases of its doctrines are admirably exhibited in the physiological researches of Cabanis, the moral dissertations of Garat and Volney, and the metaphysical disquisitions of Destutt de Tracy. (*Damiron, Hist. de Phil. en France, &c. &c.*)

IDES. (Supposed to be derived from the obsolete verb iduare, *to divide.*) One of the three epochs or divisions of the ancient Roman month. The *calends* were the first days of the different months; the *ides*, days near the middle of the months; and the *nones*, the ninth day before the ides. In the months of March, May, July, and October, the ides fell on the 15th; in the other months on the 13th. The Romans used a very peculiar method of reckoning the days of the month. Instead of employing the ordinal numbers first, second, third, &c., they distinguished them by the number of days intervening between any given day and the next following of the three fixed divisions. For example, as there were always eight days between the nones and the ides, the day after the nones was called the eighth *before* the ides, the next the seventh *before* the ides, the next the sixth before the ides, and so on. In leap years, when February had twenty-nine days, the extra day was accounted for by calling both the twenty-fourth and twenty-fifth days of that month the sixth day before the calends of March; whence the leap year got the name of bissextile (from bis, *twice*, and sextus, *sixth*). *See* BISSEXTILE.

I'DIOM. (Gr. ἴδιος, *peculiar.*) In Philology, a mode of speaking or writing foreign from the usages of universal grammar or the general laws of language, and restricted to the genius of some individual tongue. Thus, a sentence or phrase consisting of words arranged in a particular manner may be a Latin idiom; the same, arranged in a different manner, an English idiom, &c. The use of a particular inflexion of a word may also be an idiom. We also use the term idiom in a more general sense, to express the general genius or character of a language. We have a number of subordinate words to express the idioms of particular tongues: thus, a Latin idiom is a Latinism, a French idiom a Gallicism, &c. The word idiom is also not uncommonly, but incorrectly, used in the same sense with the French *idiome;* a dialect or variety of language. *Idiotisme* is the French term expressing the correct signification of the English "idiom."

I'DIOPA'THIC. (Gr. ιδιος, and παθος, *an affection.*)

A disease which does not depend upon any other disease and which is thus opposed to those diseases which are *symptomatic.*

I'DIOSY'NCRASY. (Gr. ἰδιος, συν, *with*, and κρασις, *a temperament.*) A state of constitution peculiarly susceptible of certain agents which in general produce no effect, or one perfectly different. Thus honey and coffee act with some few persons as violently aperient; very minute doses of antimony are occasionally followed by powerful emetic effects, and of mercury by salivation, &c.

I'DIOT. (Gr. ἰδιωτης, originally *a private individual.*) In contemplation of Law, one who has been born totally deficient in understanding, or has lost it by sickness, so as to have no lucid intervals: lunatic, properly speaking, one who has lucid intervals. The care of idiots and lunatics is a branch of the prerogative of the crown, and exercised ordinarily by the chancellor. By the common law persons were found idiots or lunatics by verdict of a jury on a writ de idiotâ or de lunatico inquirendo; but in later times by commissions issued, on petition from near relations, under the great seal. Commissions are also frequently issued to determine not specifically whether the party be an idiot, &c., but whether he be under such imbecility as to require protection in the management of his affairs; and such is now the more ordinary course. The custody of an idiot's estate is then entrusted to the committee of the estate.

IDIO'TICON. (Gr.) A word of frequent use in Germany, signifying a dictionary confined to a particular dialect, or containing words and phrases peculiar to one part of a country.

I'DOCRASE. (Gr. ἰδεα, *form*, and κρασις, *mixture; indicating that its forms are a mixture of the forms of certain other minerals.*) The volcanic garnet. It is of various colours, and is sometimes called volcanic crysolite or hyacinth. It occurs in the ejected masses of Vesuvius, and elsewhere. It is an alumino-silicate of lime, with about 5 per cent. of oxide of iron.

I'DOL, IDO'LATRY. (Gr. εἰδωλον, *a similitude, representation, or image;* λατρεια, *worship.*) The figures of metal, stone, or wood, by which Pagans for the most part represent their divinities, are termed *idols*, and the worship paid to them *idolatry*. This practice is expressly forbidden by the second commandment of the Decalogue, which says, "Thou shalt not make unto thyself any graven image: Thou shalt not bow down to them nor worship them,"— which must be interpreted to forbid the making of an image for the purpose of worshipping it. The absurdity and criminality of idolatry are also clearly pointed out by the light of nature. Roman Catholics, however, are accused of idolatry, upon the supposition of their performing acts of adoration to the images of Christ, the Virgin, and Saints: the adoration of the Host, or consecrated elements, is also made a charge against them. The reply which they make, that "they kneel not to the image, but to the spiritual being represented by it," is the answer of every enlightened heathen in his own case, but does not express the feelings of the multitude; nor was room allowed to the Jews for any such subterfuge.

In a wider sense, the adoration of any visible objects, such as the sun and the host of heaven (Sabianism), is idolatry; and the adoration of animals by the Egyptians. But in the more restricted signification of the word, it denotes the adoration by men of the works of their own hands; properly as images (ειδωλα), supposed to represent divine beings. Although Grecian idolatry was dignified by all the charms which art could throw around it, it appears that the most popular idols were rude and almost formless images; traditionary representations of the divinities, to many of which the vulgar notion attributed a divine origin, believing them to have fallen from heaven. Such were the Hermæ of Athens; the image of Diana (Διοπετης) at Ephesus, mentioned in the Acts; the sacred "Ancilia," or shields, of the Romans: which seem to have commanded more of the veneration of the common people than the Pallas of the Parthenon, or the Jupiter Olympius of Elis. (See *Vossius, De Origine Idololatriæ; Graves on the Pentateuch; Creuzer, Symbolik der alten Voelker; Spence's Polymetis; Mem. de l'Acad. des Inscr.* vol. xxxviii.)

I'DRIALINE. A fusible inflammable substance, found by Dumas in a mineral from the quicksilver mines of Idria in Carniola.

I'DYL. (Gr εἰδυλλιον, the diminutive of εἶδος, *form.*) A short pastoral poem. The Greek word is derived from ειδος, *form*, or *visible object;* and hence the object, or at least the necessary accompaniment of this species of poem, has been said to be a vivid and simple representation of ordinary objects in pastoral nature. But in common usage the signification of this word is hardly different from that of eclogue. The poems of Theocritus are termed Idyls, those of Virgil Eclogues; but it would be difficult to assign a distinction between the two, except what arises from the greater simplicity of language and thought which characterizes the former. Many critics, however, aver that the eclogue requires something of epic or dramatic action; the idyl only picturesque representation, sentiment, or narrative. (*See* ECLOGUE, BUCOLIC.) In English poetry, among this class may be ranked *The Seasons* of Thomson, *Shenstone's Schoolmistress, Burns' Cottager's Saturday Night, Goldsmith's Deserted Village,* &c. &c.

IGASU'RIC ACID. A name given by Pelletier and Caventou to an acid which is found combined with strychnia in the *Nux vomica* and St. Ignatius's bean.

IGNA'TIUS'S BEAN. The seed of the *Ignatia amara*, used in the Philippine Islands as a cathartic and emetic. *See* STRYCHNIA.

I'GNIS FA'TUUS. (Lat. *vain or foolish fire;* a translation of the Fr. feu follet.) A kind of luminous meteor, which flits about in the air a little above the surface of the earth, and appears chiefly in marshy places, or near stagnant waters, or in churchyards, during the nights of summer. There are many instances of travellers having been decoyed by these lights into marshy places, where they perished; and hence the names *Jack-with-a-lantern, Will-with-a-wisp:* the people ascribing the appearance to the agency of evil spirits, who take this mode of alluring men to their destruction. The cause of the phenomenon does not seem to be perfectly understood; it is generally supposed to be produced by the decomposition of animal or vegetable matters, or by the evolution of gases which spontaneously inflame in the atmosphere.

IGNI'TION. (Lat. ignis, *fire.*) The act of setting fire to, or of taking fire; as opposed to combustion or burning, which is a consequence of ignition. The term *spontaneous ignition* is applied to cases in which substances take fire without previous application of heat: thus spongy platinum is said to become spontaneously ignited when introduced into a mixture of oxygen and hydrogen gases, and to cause their combustion. The particles of steel struck off by collision with flint become ignited on passing through the air, and falling upon gunpowder ignite it, and combustion ensues. Iron wire, when red hot, is also often said to be *ignited*, or in a state of ignition; and when in that state it is plunged into oxygen gas, or into chlorine, it undergoes combustion, and burns in those gases with the further extrication of heat and light.

IGNORA'MUS. (Lat. *we are ignorant.*) In Law, the endorsement of a grand jury on a bill of indictment, equivalent to "not found." The jury are said to *ignore* a bill when they do not find the evidence such as to make good the presentment.

IGUA'NA. (Cuvier states, with reference to the derivation of this term, that it was originally a St. Domingo word, where it was pronounced by the natives *hiuana* or *igoana*, and quotes Hernandes and Scaliger as his authorities. He then proceeds to say, that Bontius regards it as derived from the Javanese word *leguan*. In this case the Portuguese or Spaniards must have transported it to America, where they transformed it into *iguana*. They apply this term to the monitor as well as to the *iguana*. The *leguan* of Bontius is a monitor. The best authorities in erpetology have adopted the Latinized *iguana* as the generic name of the reptiles under consideration.) A genus including certain large and beautiful lizards common in the tropical parts of America, some of which feed on vegetable substances, and are esteemed delicious food. The common iguana (*Iguana tuberculata*, Laur.) has accordingly received the specific names *delicatissima* and *sapidissima*. The generic name *iguana* is now restricted to those species which present the following characters:— A large thin fold of skin or dewlap under the chin; cephalic cuticular plates, polygonal, unequal in diameter, flat or carinated; a double row of small palatal teeth; maxillary teeth, with their edges finely dentilated; a crest on the back and tail; toes long and unequal; a single row of femoral pores; tail very long, slender, compressed, covered with small, equal, imbricated carinated scales.

IGUA'NIDÆ. (From *Iguana.*) The family of lizards, of which the genus *Iguana* is the type, and which is divided, according to minor modifications of the leading characters of the Iguanas, into the subgenera *Iguana* proper, *Corythophones, Basiliscus, Aloponotus, Amblyrhynchus, Metopoceros, Cyclura, Brachylophus, Enyalus,* and *Ophryœssa.*

IGUA'NINÆ. (From *Iguana.*) The *Lézards iguaniens* of French erpetologists. This extensive tribe of Lacertine Sauria is divided by MM. Duméril and Bibron into two groups, *Pleurodontes* and *Acrodontes*.

The *Pleurodontes* include the families *Iguanidæ, Polychridæ, Anoliidæ, Tropidolepididæ,* and *Opluridæ*.

The *Acrodontes* embrace the families *Galeotidæ, Agamidæ, Phrynocephalidæ,* and *Stellionidæ*.

A short and thick tongue, with base not retractable in a sheath, and with the extremity free, mobile, and very slightly cleft, is the general character of this extensive tribe.

IGUA'NODON. (From *Iguana;* and Gr. οδους, *a tooth.*) An extinct genus of gigantic herbivorous reptiles, dis-

covered by Dr. Mantell in the wealden fresh-water formation of the South of England, in the localities of Tilgate Forest, Isle of Wight, and Purbeck. The chief distinctive character of this genus is the form of the teeth, which are dentilated along the margin of the crown, as in the *iguana;* but thicker, so as to present, when worn down, a broader grinding surface. The structure by which these teeth were adapted to the cropping of coarse and tough vegetable food, such as the *Clathrasiæ* and similar fossil plants of the wealden strata may be supposed to have afforded the *iguanodon*, is thus described by Dr. Buckland:—"The teeth exhibit two kinds of provisions to maintain sharp edges along the cutting surface, from their first protrusion until they were worn down to the very stump. The first of these is a sharp and serrated edge, extending on each side downwards from the point to the broadest portion of the body of the tooth. The second provision is one of compensation for the gradual destruction of this serrated edge, by substituting a plate of thin enamel to maintain a cutting power in the anterior portion of the tooth until its entire substance was consumed in the service. Whilst the crown of the tooth was thus gradually diminishing above, a simultaneous absorption of the root went on below, caused by the pressure of a new tooth rising to replace the old one, until by this continual consumption at both extremities the middle portion of the older tooth was reduced to a hollow stump, which fell from the jaw to make room for a more efficient successor." The anterior surface of the crown of the tooth also, instead of being flat and even, was traversed by alternate longitudinal ridges and furrows, the latter serving "as ribs or buttresses to strengthen and prevent the enamel from scaling off, and forming, together with the furrows, an edge slightly wavy, and disposed in a series of minute gouges or fluted chisels; hence the tooth became an instrument of greater power to cut tough vegetables under the action of the jaw, than if the enamel had been a continuous straight line. By these contrivances also it continued effective during every stage through which it passed, from the serrated lancet point of the new tooth to its final consumption."

From the proportions which the bones of the *iguanodon* bear to those of the *iguana*, this extinct monster of a former world is calculated to have been 70 feet in length from the snout to the end of the tail; the length of the tail alone is calculated to have been 52½ feet, the circumference of the body 14½. The thigh bone of the full-sized *iguanodon* is twenty times the size of that of the *iguana*. The snout of the *iguanodon* was armed with a short but strong horn; but the long and powerful tail formed probably its most formidable instrument of attack and defence.

IL'EUM. (Gr. ειλεω, *I turn about*.) The last portion of the small intestines, terminating at the valve of the cœcum.

I'LIA. (Lat.) The flanks, or the part of the abdomen which includes the small intestines. The *os ilium* is the haunch bone, the upper part of the *os innominatum*, which supports the intestines.

I'LIAC PA'SSION. (Lat. ilia, *the bowels*.) A vomiting of bilious and fecal matter in consequence of obstruction in the intestinal canal.

I'LIAD. (Gr. Ιλιας.) The oldest epic poem in existence; commonly attributed to Homer, but according to some modern hypotheses the work of several hands. The theme of the poem is the siege of Ilium (whence its name), or Troy; or, more properly speaking, the quarrel of Achilles with Agamemnon, general of the Grecian army before that city. It consists of twenty-four books. The first book relates the origin of the quarrel; and the residue of the poem contains an account of the efforts made by Agamemnon and the chiefs who adhered to his party to conquer the Trojans without the aid of Achilles, their defeat, the pacification of Achilles, his resumption of arms in the common cause, and the death of Hector by his hand. Neither the landing of the chieftains, nor the conclusion of the war and capture of Troy, come within its range. *See* EPIC.

ILLA'TIVE CONVERSION, in Logic, is that in which the truth of the converse follows from the truth of the exposita, or proposition given. Thus the proposition "no virtuous man is a rebel," becomes by illative conversion "no rebel is a virtuous man." "Some boasters are cowards;" therefore, à converso, "some cowards are boasters."

ILLUMINA'TI, or THE ENLIGHTENED. A secret society, formed in 1776, chiefly under the direction of Adam Weishaupt, professor of law at Ingolstadt in Bavaria. Its professed object was the attainment of a higher degree of virtue and morality than that reached in the ordinary course of society. It numbered at one time 2000 members. It was suppressed by the Bavarian government in 1784. It has been supposed that this and some other secret societies were actively engaged in preparing the way for the French revolution; but of this no satisfactory proof has been adduced. (See the *Ency. von Ersch and Gruber*.)

ILLUSTRA'TION, in Rhetoric, appears to differ from Comparison or Simile in this only, that the latter is used merely to give force to the expression; the former to throw light upon an argument. The term illustration is, however, sometimes used in a wider sense, in which it seems to comprehend example, which is the recital of a particular fact or instance evincing the truth of a general proposition laid down in the argument; and parable, which is a species of symbolical narrative, in which the actors and events are intended to represent certain other actors and events in a typical manner. *See* PARABLE.

I'MAGE. (Lat. imago.) In Rhetoric, a term somewhat loosely used; but which appears generally to denote a metaphor dilated, and rendered a more complete picture by the assemblage of various ideas through which the same metaphor continues to run, yet not sufficiently expanded to form an allegory.

I'MAGE. A representation of the Deity in stone, wood, or metal. (*See* art. IDOL.) The custom of representing Christ, the Virgin, and the Saints by images in the churches, which forms a principal feature of Roman Catholic worship, is an ancient but not a primitive practice. For the principal events in the history of Christian image worship, see art. ICONOCLASTS.

I'MAGE, in Optics, is the spectrum or appearance of an object, made by reflection or refraction; or the *image* of an object may be more correctly defined as the locus of all the pencils of converging or diverging rays emanating from every point of the object, and received on a surface. It is by means of optical images that vision is effected. The eye is an assemblage of lenses which concentrate the rays emanating from each point of the object on a tissue of very delicate nerves called the *retina*, where an exact image or representation of the object is formed; and it is this image which is perceived or *felt* by the retina.

The brightness of an image depends evidently on the quantity of light concentrated in each point. Setting aside the effects of aberration, the brightness must therefore be proportional to the apparent magnitude (as seen from the object) of the mirror or lens by which the rays are reflected or refracted, multiplied by the area of the object and divided by the area of the image. But the apparent magnitude of the lens, as seen from the object, is proportional to the square of the diameter of the lens divided by the square of the distance of the object; and the area of the object divided by the area of the image is equal to the square of the distance of the object divided by the square of the distance of the image from the lens: therefore the brightness of the image is proportional to the square of the diameter of the lens divided by the square of the distance of the image from the lens; that is to say, the brightness or degree of illumination of the image depends only on the apparent magnitude of the lens, as seen from the image, and not in any way on the distance of the object. When the object and its image are only physical points, and have no apparent magnitude, as stars for example, the brightness of the image is simply proportional to the magnitude of the lens, or to the square of the diameter of the aperture of the telescope; and for this reason certain stars are rendered visible by large telescopes, while their light is too feeble to be perceived by smaller ones.

The images of external objects are painted on the retina in a reversed position, and from the retina the impressions are ransmitted to the sensorium by the optical nerves. *See* EYE, OPTICS.

I'MAGERY may be defined as the generic term for *similes*, *allegories*, and *metaphors*, or such rhetorical figures as denote similitude or comparison.

IMA'GINARY QUANTITIES, or IMPOSSIBLE QUANTITIES, in Algebra, are the even roots of negative quantities, or the imaginary results of some impossible operation. The square root of any positive number may be affected indifferently with the positive or negative sign; thus $\sqrt{9a^2} = \pm 3a$; because $+3a$ or $-3a$, raised to the square, equally produce $9a^2$. But if the number or quantity is negative, the extraction of its square root is impossible, because the square of any quantity, whether positive or negative, is essentially positive; that is to say, a negative quantity cannot be the square of any real quantity whatever. The symbolical expressions $\sqrt{-9}$, $\sqrt{-4a^2}$, $\sqrt{-5}$, indicate operations which are impossible; and hence they are designated *imaginary* expressions. But though the quantities denoted by these symbols have no real values, the symbols themselves may have all the algebraic operations performed on them which can be performed on real quantities. Thus, $\sqrt{-9} = \sqrt{9}\cdot\sqrt{-1} = 3\sqrt{-1}$; and $\sqrt{-4a^2} = \sqrt{4a^2}\cdot\sqrt{-1} = 2a\sqrt{-1}$. Such expressions are of very frequent occurrence in the higher analysis, and sometimes lead to results of the greatest importance, which it would be difficult, if indeed possible, to obtain in another way. (See *Peacock's Algebra*.)

IMAGINARY ROOTS OF EQUATIONS, are roots

which can only be indicated by imaginary expressions. D'Alembert first demonstrated that every imaginary root of an equation can be reduced to the form $a + b\sqrt{-1}$, where a and b are real quantities; and from this it is proved that if an equation have a root of the form $a + b\sqrt{-1}$, it has also another of the form $a - b\sqrt{-1}$; so that imaginary roots always enter an equation by pairs, or their number is always even.

IMAGINATION, in Metaphysics, may be said, in its widest sense, to be synonymous with invention, denoting that faculty of the mind by which it either "bodies forth the forms of things unknown," or produces original thoughts or new combinations of ideas from materials stored up in the memory. It would be vain to enumerate the various definitions of this term, or to attempt to give even an abstract of the diversity of views entertained by philosophers respecting the nature and extent of its operations. While some (and among these Reid and Addison) limit the domain of this faculty so far as to teach that it is nothing more than a *lively conception* of the objects of sight, differing from conception only as a part from the whole; others, like Dugald Stewart, place it in the foremost rank of the mental faculties, attributing to its operation the origination and development of the sublimest and boldest thoughts in all the departments of human knowledge. Dr. Reid's chapter *on the Train of Thought in the Mind* gives a vivid though simple picture of the power of the imagination; while, at the same time, it exhibits a tolerably faithful specimen of the difficulty of treating this subject, owing to a want of precision in the definition of the term. In many philosophical disquisitions imagination is used as nearly synonymous with *fancy*. But it should seem that this is an erroneous application of the term; for, as Dugald Stewart observes, the latter should rather be considered as that peculiar habit of association which presents to our choice all the different materials that are subservient to the efforts of the former, and which may therefore be considered as forming its groundwork. *See* Association. Poetry.

IMA'N. An inferior order of ministers of religion in the Turkish empire. The chief imân of each mosque (Imam'ul-Haikh) performs the ordinary civil functions which in Europe have been in most countries assigned to parish priests, assisting at the circumcision, marriages, burials, &c. of his parishioners. He presides over the assembly of the faithful at the ordinary prayers; but the solemn noon prayer on Friday is under the superintendence of the Khatib, a higher minister (who is also called from that circumstance the *Imam'ul Djumâ*, or Friday Imân). The legitimate successor of Mahomet, in whom, in theory, the temporal and ecclesiastical government of Islam should reside, is termed *Imam* by way of pre-eminence; but the Mussulmans are not agreed among themselves as to the character of this dignity, or as to those who have rightfully borne it. The Persians reckon twelve legitimate Imams, of whom they believe the last (Mahadi) to be still living. (See *Taylor's Hist. of Mohammedanism*, ch. viii.)

IM'BRICATED. In Botany, a term used in speaking of the arrangement of bodies, to denote that their parts lie over each other in regular order like the tiles upon the roof of a house; as the scales upon the cup of some acorns: also applied in speaking of the æstivation of petals or leaves, to denote that they overlap each other at the margin without any involution.

IMBRO'GLIO. (A word borrowed from the Italian brogliare, *to confound or mix together*; whence the French brouiller and English embroil.) In literary language, the plot of a romance or a drama, when much perplexed and complicated, is said to be an "imbroglio." The small burlesque theatrical pieces so termed by the Italians derive their ludicrous character from a similar species of absurdity.

IMITA'TION. (Lat.) In Music, a species of composition in which each part is made to imitate the other. Sometimes the motion or figure of the notes is only imitated, and frequently by a contrary motion, making what is called a *retrograde imitation*, or *imitazione cancherizante*. Imitation, according to M. Brossard, differs from a *fugue* in that the repetition must be a second, third, sixth, seventh, or ninth; whereas in a fugue the repetition must be in the unison fourth, fifth, or octave, and the intervals exactly the same in the *comes* and *guide*.

IMME'RSION (Lat. immergo, *I plunge under*), in Astronomy, denotes the disappearance of any celestial object behind another or in its shadow. Thus in an eclipse of one of Jupiter's satellites, the immersion takes place when the satellite disappears behind the body of the planet, or enters into the planet's shadow; and in an occultation of a planet or fixed star by the moon, the immersion is the disappearance of the star or planet behind the body of the moon. In like manner, the reappearance of the body is called its emersion. The immersions and emersions of fixed stars occulted by the moon, are phenomena of great importance for correcting the lunar tables.

IMMERSION, BAPTISM BY, seems to have been the most ancient mode adopted in the Christian church. The *trine* immersion, in honour of the three persons of the Divinity, is mentioned by Tertullian, and prescribed in the Sacramentary of Gregory the Great; but *single* immersion was held valid by that pope, and his decision was confirmed by the fourth council of Toledo, A.D. 633. (*Riddle's Christian Antiquities*, 462.)

IMMOLA'TION. (Lat.) A ceremony used in the Roman sacrifices, which consisted of throwing upon the head of the victim some sort of corn or frankincense, together with the *moal*, or salt cake, and a little wine.

IMMU'NITY. In Jurisprudence, legal freedom from any legal obligation. Thus the phrase "ecclesiastical immunities" comprehends all that portion of the rights of the Church, in different countries, which consists in tho freedom of its members, or of its property, from burdens thrown by law on other classes.

I'MPACT. (Lat. impingo, *I impinge on any thing.*) In Mechanics, the instantaneous action of one body on another to put it in motion. If the body moves in the direction of the stroke, the impact was direct; if in a different direction, the impact was oblique.

IMPA'GES. (Lat.) In Architecture, a word usually taken to mean the rails of a door.

IMPA'LEMENT. In Heraldry, the division of a shield palewise, when the shield is said to be *party per pale*. *Impalement per baron et feme* is the division which takes place on marriage; when the husband's coat is borne on the dexter side of the pale, and the wife s on the sinister. Formerly, the husband's and wife's arms were impaled *by dimidiation*; that is, the dexter half of the husband's coat impaled with the sinister half of the wife's: and this inconvenient mode of marshalling was pursued in French heraldry down to the period of the Revolution.

Impalement. A species of punishment formerly in use among the Turks and some barbarous nations, which consisted in thrusting a stake through the body, and thus leaving the victim to a lingering death. Instances are on record of persons enduring this horrid torture for several days before death released them from agony. (See *Shaw's Travels in Barbary*.)

IMPANA'TION, in Theology, otherwise termed *Assumption*, signifies the substantial union of the body and blood of Christ with the elements of the eucharist without a *change* in their nature. The word appears to be first used in the controversy about the real presence in the 11th century, and to be applied, by the supporters of transubstantiation, to the less material doctrine of Berengarius and his followers. It has since been objected, by Roman Catholics, to the Lutheran theory, that it revived the old error of impanation. The supporters of the opinion of Berengarius were sometimes termed *Adessenarii*; from the word adesse, *to be present*.

IMPA'RLANCE. (Fr. parler, *to speak*.) A mode of delaying proceedings in a civil action by petition to the court for further time. General imparlance was to the next term; special imparlance to a specified day, which might be in the same term. The practice of imparlance appears to be abolished by 2 W. 4. c. 39., except as to actions not commenced under the process given by that act.

IMPASTA'TION. In Sculpture, the mixture of different matters bound together by means of cements capable of resisting the action of fire or air.

IMPEA'CHMENT. (From the Latin impetere, *to prosecute*.) A species of process against persons accused of treason, or high public crimes and misdemeanours of an inferior description. The first regular instances of this proceeding appear, according to Mr. Hatsell, on the rolls of parliament in the latter end of the reign of Edward III. Before that time the Lords seem to have exercised a high but irregular jurisdiction over state offences, at the prayer of the crown or of private persons. But in the case of Richard Lyon, 1376, we first find the Commons appearing in their public capacity as prosecutors: and several similar instances occur in the course of the following century. But from the reign of Henry VI. to that of James I. impeachments seem to have fallen into disuse; bills of attainder, and prosecutions in the Star Chamber, having been prosecuted in their stead. In the seventeenth year of James I. this form of proceeding was revived against Sir Giles Mempesson for having procured illegal patents, and from that time to the present has been the regular constitutional form of accusation for state offences. The form of the accusation exhibited by the Commons is styled *the articles of impeachment*. It is an undoubted right of the Commons to exhibit such articles against a peer for treason, or any other high crimes and misdemeanours; but it has been doubted whether the Lords have jurisdiction in capital cases over a commoner in this proceeding. In one instance (in 1681) they refused to do so, but have in several other instances admitted their competency. Managers are appointed by the Commons to conduct the prosecution before the Lords. In case of an impeachment of a peer for

treason, it is usual to address the crown to appoint a lord high steward; but the appointment of such an officer does not seem essential to the conduct of an impeachment. By 12 & 13 W. 3. c. 2. it is enacted that a pardon under the great seal shall not be pleadable to an impeachment. This, however, does not deprive the king of his prerogative of pardoning after conviction. It was determined, on the impeachment of Warren Hastings, that this proceeding in the Lords is not put an end to by the prorogation or dissolution of parliament; and an act was passed to prevent prorogation or dissolution from having the effect of putting a stop to the previous proceedings in the House of Commons. Judgment on impeachment must proceed on the same evidence which would be required in the ordinary courts of justice; in which respect this proceeding differs from that by bill of attainder.

IMPE'NETRABI'LITY. In Physics, one of the essential properties of matter or body. It is a property inferred from invariable experience, and resting on this incontrovertible fact, that no two bodies can occupy the same portion of space in the same instant of time. Impenetrability, as respects solid bodies, requires no proof; it is obvious to the touch. With regard to liquids, the property may be proved by very simple experiments. Let a vessel be filled to the brim with water, and a solid incapable of solution in water be plunged into it; a portion of the water will overflow exactly equal in bulk to the body immersed. If a cork be rammed hard into the neck of a phial full of water, the phial will burst, while its neck remains entire. The disposition of air to resist penetration may be illustrated in the following way: — Let a tall glass vessel be nearly filled with water, on the surface of which a lighted taper is set to float. If over this glass a smaller cylindrical vessel, likewise of glass, be inverted and pressed downwards, the contained air maintaining its place; the internal body of the water will descend, while the rest will rise up at the sides, and the taper will continue to burn for some seconds, encompassed by the whole mass of liquid. (*Leslie's Elements of Natural Philosophy*.)

IMPE'NNATES, *Impennes*. (Lat. in, and penna, *a wing*.) The name of a tribe of swimming birds, having short wings covered with feathers resembling scales. The penguin (*Aptenodytes*) is a good example of this group.

IMPE'RATIVE MOOD. (Lat. impero, *I command*.) That form of the verb which denotes command, entreaty, or, in general, desire. *See* GRAMMAR.

IMPE'RFECT CADENCE. In Music. *See* CADENCE.

IMPE'RFECT CONCORDS. In Music, such as are liable to change from major to minor, or the contrary, as are thirds and sixths; still, however, not losing their consonancy.

IMPE'RFECT NUMBER. A perfect number is one whose aliquot parts, added together, make a sum equal to the number itself. An imperfect number, consequently, is one such that the sum of its aliquot parts, or divisors, is not equal to the number itself. Thus 12 is an imperfect number; for the sum of its divisors, 1, 2, 3, 4, 6, is 16, which is greater than 12.

IMPE'RFECT TENSE. In Grammar, that modification of a verb which expressses that the action or event of which we speak was at a certain time to which we refer in an unfinished state. This is in English designated by the auxiliary "was," joined with the present participle.

IMPE'RIAL. (Fr.) In Architecture, a species of dome whose profile is pointed towards the top and widens towards the base, thus forming a curve of contrary flexure.

IMPE'RSONAL VERBS, in Grammar, are those used only in the third person; as ἔξεστι, licet, *it is lawful*. It is quite clear that every verb, whether active or passive, must have a necessary reference to some noun, either expressed or understood, for its nominative; and hence the doctrine of impersonal verbs has been justly rejected by the best grammarians, both ancient and modern. *See* GRAMMAR.

IMPETI'GO. (Lat. impetire, *to infest*.) An eruption of small pustules, sometimes called the moist tetter: the vesicles discharge an acrid ichor. Something of this kind is often produced by particular trades, where irritating substances are applied to the skin. Cleanliness, cooling ointments, and occasionally the nitrated mercurial ointment much diluted, are useful. Harrowgate water and baths have been recommended, and mild aperients. The eruption is not contagious.

I'MPETUS. (Lat. *force*.) In Mechanics, the same with momentum or force. *Impetus*, in Gunnery, is the altitude through which a heavy body must fall to acquire a velocity equal to that with which the ball is discharged from the piece.

I'MPLEMENTS, AGRICULTURAL. Almost all the operations of agriculture may be performed by the plough, the harrow, the scythe, and the flail; and these are the sole implements in the primitive agriculture of all countries With the progress of improvement, however, many other implements have been introduced; the more remarkable of which are the drill-plough, the horse-hoe, the winnowing machine, the threshing machine, the hay-making machine, and the reaping machine. The object of all these implements and machines is to abridge human labour, and to perform the different operations to which they are applied with a greater degree of rapidity and in a more perfect manner than before.

I'MPLEMENTS, HORTICU'LTURAL. The essential implements of horticulture are the spade and the pruning knife. The rake might be added, but it can be done without; because if seed be sown on a rough surface, it may be covered by beating that surface smooth with the spade; and if on a smooth surface, it may be covered by scattering with the spade a very thin sprinkling of earth over it. Even the pruning knife might be dispensed with; because culinary vegetables might be pulled up by the roots, or cut off at the surface of the ground with the spade; and fruit trees will produce crops without pruning, as by disbudding and thinning with the finger and thumb as large fruit may be grown as ever will be produced by the use of the knife. It must be confessed, however, that the knife and the rake are very nearly essential instruments of horticulture. With the progress of horticulture a great number of implements, instruments, utensils, and machines have been brought into use. Of these may be mentioned the hoe for stirring the soil and cutting up weeds; and this implement on a larger scale in warm countries is used as a substitute for the spade. The watering pot in modern gardening is an important utensil, and the syringe a machine that can scarcely be dispensed with. In the forcing department, we have the thermometer, the hygrometer, and various contrivances for supplying and regulating heat, admitting or excluding air, and producing artificial vapour or rain.

IMPLICA'TION. (Lat. implico, *I evolve*.) In Law, an inference necessarily arising from something declared. Thus contracts are said to be either express or implied. *See* CONTRACT.

IMPLU'VIUM. (Lat.) In Ancient Architecture, the outer part of the court of a house which was exposed to the weather. In the summer time it was the practice to stretch an awning over it.

IMPO'NDERABLE SUBSTANCES. Heat, light, electricity, and magnetism are so called, being supposed to depend upon very subtile forms of matter of inappreciable weight.

IMPORTS AND EXPORTS. The articles imported into and exported from a country. *See* COMMERCE.

IMPO'SING (Fr. imposer), in Printing, is the arrangement of the pages of a sheet upon the imposing stone in their proper order, so that when printed and the sheet folded they will follow each other consecutively; putting the furniture about them, with the chase; and wedging them up, so as to be ready to print..

IMPOSI'TION OF HANDS (Lat. impono, *I place upon*), is maintained in the English and other churches, as conformable to the apostolic practice and that of the earliest ages, in which confirmation and the ordination of priests and deacons are supposed to have been accompanied with the performance of this ceremony. In Acts vi., the apostles lay their hands on those appointed to be deacons; in Acts viii. and xix., the converts who had been already baptized by Philip and John are in the same manner confirmed by Paul and the other apostles.

IMPOSSIBLE QUANTITY. *See* IMAGINARY QUANTITY.

I'MPOST. (Lat. impono, *I lay on*.) In Architecture, the capital of a pier or pilaster which receives an arch. The impost varies with the order whereto it is applied. Sometimes the whole of the entablature serves as an impost to an arch. The term is applicable to any supporting piece. *Impost* is also frequently used as synonymous with tax or public burden.

IMPRE'SSION. (Lat. imprimo, *I press upon*.) In the Fine Arts, the sensation on the mind which is excited by a work of art. The word is also used to denote a copy of an engraving drawn off from the plate or block on which the subject is engraved.

IMPRE'SSMENT. The forcible levying of mariners for the king's service at sea. The power of impressment is a branch of the king's prerogative. It is mentioned in the statute 2 Richard 2. c. 4. as a recognized usage. Various classes of mariners are exempted from it by particular statutes. The officer impressing acts under an impress warrant for that especial purpose; but the regularity of this instrument is carefully watched by the courts, and criminal informations have been also granted against officers guilty of unnecessary severity or acts of private malice in carrying it into execution. (See, for arguments in favour of maintaining this practice, *Quart. Rev.* vol. xlix. p. 496, &c.; against, *Wealth of Nations*, M'Culloch's ed., note xii.)

IMPRIMA'TUR. (Lat. *let it* (*the book*) *be printed*.) The term applied to the privilege which, in countries subjected to the censorship of the press, must be granted by a public functionary appointed for the purpose before

any book can be printed. This formula was much used in English books printed in the 16th and 17th centuries; and this permission is even still vested in some of our own universities, especially in Scotland, where it is nothing unusual to find on the title-page of some works recommended to public favour by the senatus academicus the "imprimatur" of the principal.

IMPRI'NT. (Fr. imprimer.) The designation of the place where, by whom, and when a book is published, always placed at the bottom of the title. Among the early printers it was inserted at the end of the book, and is styled the colophon. By the act 39 Geo. 3. c. 79., every printer is obliged to affix his name and residence to each article he shall print, and if it consists of more than one leaf, then upon the first and last leaves, under a heavy penalty; but there are some exceptions.

IMPRO'MPTU. (Lat. *in readiness.*) In Literature, any short and pointed production supposed to be brought forth on the spur of the moment; generally of an epigrammatic character.

IMPRO'PER FRACTION, in Arithmetic and Algebra, is a fraction whose numerator is equal to, or greater than, its denominator.

IMPROPRIA'TION, in Law, is where the tithes, glebe, or other ecclesiastical dues of a parish are in the hands of a layman. The religious societies having, at the time of the Reformation, the property of many benefices in their hands, clauses were inserted in the acts by which they were dissolved to give that property absolutely to the king, by whom it was granted out to lay proprietors. In common language, such benefices are said to be *impropriated* as are in the hands of laymen; such as are held by spiritual corporations, sole or aggregate, are termed *appropriated.*

I'MPROVISATO'RE. (Lat. improviso, *unforeseenly, unpremeditatedly.*) An Italian word, signifying a person who has the talent of composing and reciting a suite of verses on a given subject immediately and without premeditation. This peculiar talent, thus restricted, appears to belong, almost exclusively, to the Italian language and people. Much, no doubt, of the facility of these improvisatori, which appears almost preternatural to one unaccustomed to hear them, arises from the peculiar ease and flexibility of their language, and its richness in rhymes. But this circumstance will not wholly account for so singular a national faculty; for, about the time of the revival of letters, Italy possessed improvisatori in Latin as well as Italian. Many poets have enjoyed considerable celebrity in their day from their success in this mode of composition; but we are not aware that any of their poems have acquired a permanent celebrity, although often taken down from their recitation. Tuscany and the Venetian States have been most famous for the production of improvisatori, especially Sienna and Verona; in which latter city the talent seems to have been perpetuated by succession. The chevalier Bernardino Perfetti, the most famous of all these reciters, was of Sienna: he flourished in the first half of the 17th century. He is said to have possessed unbounded erudition, and to have been able to pour forth extempore poetical essays on the most abstruse questions of science. There have been many distinguished females possessed of this talent (improvisatrici). Corilla, the most celebrated of them, was of Pistoia in Tuscany. She was the original of Madame de Staël's *Corinne.* She received in 1776 the laureate crown at Rome, an honour which had also been accorded to Perfetti. Germany is said to have produced one noted improvisatrice, Anna Louisa Karsch. There appears no reason why the term improvisation should not also be applied to the delivery of unpremeditated discourses in prose. It is the exertion of a very similar faculty, perfected in the same manner by habit to a degree almost inconceivable by those not accustomed to witness its exercise. It is, however, much more general. The North American Indians are represented to possess it in a high degree. In Europe, it is most generally to be found in the pulpit. Public secular oratory of this unpremeditated description is far more common in England, and the power much more sedulously cultivated, than in any Continental country. (See *Forsyth's Italy; Ed. Rev.* vol. xxii.; *Encyc. Metr.*)

INAU'GURA'TION (Lat. inaugurare, *to take omens*), was originally applied to the Roman ceremony of admission to the college of augurs, or soothsayers, or to the selection of a proper site for the erection of temples or other national edifices; but it afterwards received a more extended signification, and is now used in a sense nearly synonymous with the *consecration* of a prelate, or the *coronation* of a king or emperor. It means also an introduction to any office with certain ceremonies.

INCA, or YNCA. A name given by the Indians of ancient Peru to their kings and princes of the blood. The empire of the Incas, founded, according to tradition, by the celebrated Manco Capac, extended over the tableland of the Andes, from Pasto to the neighbourhood of Chili, as well as the low lands on the coast. It was destroyed by the Spaniards under Pizarro and Almagro. The blood royal of the Incas is preserved, or believed to be so, among the Indians of the present day; and Tupac Amaru, who carried on a long and nearly successful insurrection against Spain in the latter part of the last century, professed to be descended from them.

IN CÆNA DOMINI. (Lat. *at the Lord's Supper.*) The name of a celebrated papal bull, containing a collection of extracts from different constitutions of the popes, comprising those rights which, since the time of Gregory VII., have been uninterruptedly claimed by the Roman see, and a proclamation of anathema against all who violate them. It was annually read on Holy Thursday, whence it receives its name; but lately on Easter Monday. The sects of heretics are cursed in it by their several designations. A copy of the bull is hung up at the door of the churches of St. Peter and St. John Lateran; and all patriarchs, primates, bishops, &c., are required to have it read once or more annually in their churches.

INCANDE'SCENCE. (Lat. in, and candere, *to be warm.*) The luminosity exhibited by a substance when heated up to a certain point.

INCANTA'TION. (Lat. in, and canto, *I sing.*) A form of words combined with certain ceremonies and mixtures of heterogeneous substances used by the ancients for many superstitious purposes. They were most commonly resorted to by unsuccessful lovers; in which case they were termed *love potions*, or *philtres*, which see.

INCARCERA'TION. (Lat.) Literally, imprisonment. In Surgery, this term is generally applied to ruptures or herniæ, with the same meaning as *strangulation;* but, according to Scarpa, an *incarcerated* hernia is that in which the course of the intestinal matter is interrupted without any considerable injury of the bowel itself; whereas in *strangulated* hernia the vitality of the bowel is affected, or there is organic injury of its coats. The functions of the merely incarcerated intestine are healthily resumed upon its return into the abdomen, which is not the case where true strangulation has taken place.

INCARNA'TION. (Lat. caro, *flesh.*) A word in common use among theologians to express the union of the Godhead with the Manhood in Jesus Christ. St. John says, "The Word was made flesh, and dwelt among us;" a text sufficiently explicit, when coupled with other expressions respecting the divine nature of the Word, to maintain the doctrine of the incarnation among the vast majority of the Christian world. But the subtle inquiries which men have instituted into the manner and nature of this union have given rise to many varieties of opinion, and to many sects which have incurred the reproach of heresy. Not the Socinians only, but the Arians and Sabellians also, are led necessarily by their premises into heterodoxy upon this point; the Nestorians, however, and Eutychians, may be considered the principal sects which have joined an orthodox belief, as to the relations of the three persons of the Trinity one to the other, with peculiar conceptions of the manner of the union of the two natures in Jesus Christ. (See the respective articles.)

The real manner of this union, or indwelling of the God in the Man, is allowed to be a mystery such as cannot be fully apprehended by the human intellect. It is easier to point out the errors which beset its investigation than to express in words the true doctrine. The phrase, "The Word was made flesh," cannot imply that the divinity was lost and annihilated in becoming flesh; nor that it changed its own nature and was turned into humanity. In either of these cases, Christ would cease to be a divine being while on earth. Nor did the Godhead inspire the Manhood after the manner in which the Prophets had been inspired in earlier times; for the terms applied to Christ are of a very different kind. Nor, on the other hand, could the humanity be lost and absorbed in the divinity, which would seem to destroy the sympathy with which the man Christ regarded mankind, upon which so much of the superstructure of his religion is raised.

INCE'NDIARY. (Lat. incendo, *I burn.*) Literally, one who sets fire wilfully to a building or stores; but it is used also in a metaphorical sense for any political agitator who seeks to inflame the minds of the people. *See* ARSON.

INCENSE. *See* FRANKINCENSE.

INCE'PTIVE. (Lat. incipio, *I begin.*) A word used by Dr. Wallis to express such *moments* or first principles as, though possessed of no magnitude themselves, have yet the power of producing it by being extended or enlarged. Thus a point or a line, though the former has no proper magnitude and the latter no breadth, are both said to be *inceptive* of enlargement. In the Latin language *inceptive* or *inchoative* verbs (the latter term being derived from the Lat. inchoare, *to begin*) are those which, according to grammarians, are characterized by the termination *sco* or *scor* added to their primitives, and are expressive of a commencement of increase or augmentation of the qualities indicated by the words from which they are derived: as *augere*, to increase; *augescere*, to begin to increase: *pallere*, to be pale; *pallescere*, to grow pale.

INCE'RTUM O'PUS. (Lat.) In Ancient Architecture, a species of walling whose face exhibits an irregularly formed masonry, not laid in horizontal courses.

INCH. A measure of length; the twelfth part of a foot.

INCH. A word used as a prefix to certain small Scottish islands, as Inch-Keith, Inch-Garvie. It is derived from the old Irish or Gaelic word inis, signifying an island.

I'NCIDENCE. (Lat. incido, *I fall upon*.) The meeting of one body with another. The term *angle of incidence* is used by writers on mechanics and optics in different senses. Thus, in the case of a body striking against a plane, the angle of incidence is by some understood to signify the angle formed by the line in which the body moved with a straight line perpendicular to the plane; while others use the term to denote the angle which the line of incidence makes with the plane itself. When light or any elastic body is reflected from a surface, the angle of incidence is equal to the angle of reflection; and in the case of refraction, the sine of the angle of incidence has to the sine of the angle of refraction a constant ratio.

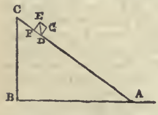
I'NCIDENT. In Law, something necessarily appertaining to and depending on another, which is termed the principal.

INCINERA'TION. (Lat. incinero, *I reduce to ashes*.) The combustion of organic substances for the purpose of obtaining their ashes or incombustible residue.

INCI'SORS, *Incisores*. (Lat. incido, *I cut*.) The teeth implanted in the intermaxillary bones of the upper jaw, and in the corresponding place in the lower jaw, and which are generally shaped for the purpose of cutting or coarsely dividing the food.

INCLINA'TION. (Lat.) A term of frequent occurrence in geometry, mechanics, physics, and astronomy. It is in all cases measured by an angle. Thus, the *inclination of the orbit of a planet* is the angle between the plane of its orbit and the plane of the ecliptic. In the history of geometry, the *problem of inclinations* is a subject that was treated of by Apollonius in two books, which are lost, but of which a description has been given by Pappus. The problem proposed was this: "To insert a straight line of a given magnitude, and tending to a given point, between two lines which are given by position." The problem was restored by Marinus Ghetaldus; and various other investigations have since been given by the method of the ancient analysis.

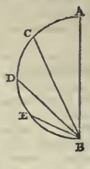
INCLI'NED PLANE. One of the five simple mechanical powers. The theory of the inclined plane is easily deduced from the decomposition of forces. Let



A C be the position of the plane, B C its altitude, and A B the horizontal distance of the foot of the plane from the perpendicular B C. Suppose a load to be placed on the plane at D, and let it be required to determine the relation between its whole weight and its tendency to descend along the plane. Let D E denote the vertical pressure of the weight, and decompose this into D F parallel to the plane, and F E perpendicular to it; and complete the parallelogram F G. Now the part F E is supported by the resistance of the plane; there remains, therefore, only the force represented by F D to urge the descent of the weight along the plane. But the triangle D F E is obviously similar to C B A, and therefore D F is to D E as C B to C A; that is, the force of descent along the plane is to the whole weight of the body as the height of the plane to its length, or as the sine of its elevation is to radius. The force, therefore, which is required to raise a body along the plane, is less than that which is required to raise it perpendicularly in the same proportion.

This fundamental proposition was first demonstrated by Stevinus of Bruges, but by a very different process of reasoning. He supposed a chain or chaplet composed of equal links to be thrown over the triangle A B C, and the two ends to be united a little below the base A B. It is evident that this chain would remain at rest, for on altering its position each link would be succeeded by a similar one in the same situation; and if it began to move of itself it would move for ever, a supposition which is absurd. But the part below the base, being suspended equally at both extremities, is evidently in a state of equilibrium; therefore the part which hangs along the perpendicular B C must balance the part lying along the inclined plane; and the weights of these two parts being as their lengths, it follows that a weight placed on the plane is to the force required to sustain it as the length of the plane to its height.

There are two properties connected with the motion of bodies on inclined planes which deserve to be noticed. The first is, that the velocity acquired by a body in descending from any altitude to a horizontal plane is the same when it reaches the horizontal plane, whether it has been allowed to fall freely in the vertical, or been constrained to move along an inclined plane at any angle of elevation. The second is, that the times of descent through all chords of the same circle to the lowest point are equal, and equal to the time the body would take to fall through a height equal to the diameter of the circle.



Thus, let A B be the diameter, and C B, D B, and E B chords of a circle; the time a heavy body would consume in falling vertically through the diameter is the same as that in which it would roll down the inclined plane C B, or D B, or E B. In other words, bodies placed at A, C, D, and E, and abandoned at the same instant to the action of gravity, would arrive at B at the same time. In these propositions it is supposed, of course, that there is no resistance from friction.

INCLO'SURE. (Lat. includo, *I shut up*.) This term, in a general sense, is one of the first acts of appropriation, since in a new country when any portion of land is purchased, or taken possession of, it is inclosed; that is, surrounded by a boundary line, indicated by certain objects, natural or artificial, or of both kinds. In a particular sense, to inclose land is to divide it into fields, and surround these by fences, in order that each field may be devoted to a particular description of culture. If nothing farther than the cultivation of plants of different kinds were carried on in the fields of a farm, their subdivision by fences would be altogether unnecessary; but as in most cases fields are kept alternately under tillage and pasture, it is desirable to have fences to confine the pasturing animals to the field appropriated for their use.

INCLU'SA. (Lat. includo, *I inclose*.) The name of a tribe of shell-bearing Acephalous Mollusks in the system of Cuvier, characterized by the closed state of the mantle, which every where surrounds and envelopes the body, leaving only a narrow aperture for the passage of the foot, and being prolonged posteriorly into two siphons projecting beyond the shell, which is always open at its two extremities. The bivalves of this family are remarkable for their powers of burrowing and excavating clay, sand, wood, or even stony rocks; and many of the genera secrete, in addition to the ordinary valves, a calcareous lining to their burrows, which forms a tube surrounding the valves themselves. The relative proportions of the tube and valves well illustrate the so-called law of the "balance of organs," the valves becoming diminished in size as the external sheath is more developed. In the ship-borer (*Teredo navalis*), which has the longest tube, the valves are of the smallest size, being reduced to the office of mere boring instruments, instead of serving to protect the soft parts of the animal. In the watering-pot shell (*Aspergillum*, Lam.) they cease to be moveable organs, and are blended or confluent with the external tube; this is dilated at the anterior extremity, which is surrounded with a projecting radiated ridge, and closed by a convex plate, perforated like the mouth of a watering pot.

INCLU'SI, or RECLU'SI. (Lat. *shut up*.) In Ecclesiastical History, a class of religious persons who lived as hermits in single cells, generally attached to monasteries, sometimes in the neighbourhood of villages and towns,—under the law of not leaving them unless in case of extreme necessity, and with the approbation of the bishop; whose seal, or that of the abbot, was impressed on its door. The cells are said to have been commonly twelve feet in length and breadth. Nuns became sometimes, but more rarely, recluses.

INCO'GNITO (Ital. *unknown*), abbreviated into *incog.*, denotes the disguise resorted to by the great when they are unwilling to be recognized. It consists either in assuming a different name or title for the nonce, or in travelling from one place to another without a retinue or other marks of distinction.

INCOMBU'STIBLE CLOTH. This term was originally applied to cloth with which asbestus was interwoven; on burning away the fibre, the incombustible mineral texture remained.

More recently, cloth and other materials have been rendered to a great extent incombustible by impregnating them with certain saline substances, which, upon the application of fire, form a species of glaze upon the goods, and prevent them burning with flame by protecting them from the necessary access of air. (*See* COMBUSTION.) Borax, alum, and phosphate of soda, or ammonia, are the most effectual salts for this purpose; and by properly applying them, with starch, if to muslin dresses, curtains, or bed furniture, or with size to paper hangings and scenery, these several articles may be rendered incapable of burning with flame, and thus serious accidents by fire prevented. Wood may also be rendered comparatively incombustible by soaking it in solutions of the above salts. *See* ASBESTUS.

INCOMME'NSURABLE. Two numbers or homogeneous quantities of any kind are said to be incommensurable when they have no common measure, or when no number or quantity of the same kind can be found which will divide them both without a remainder. Thus the numbers 21 and 22 are incommensurable. The

side of a square and its diagonal are incommensurable lines, as is proved by Euclid in his tenth book. Numbers are said to be *incommensurable in power* when their squares or second powers are incommensurable; as 2 and 3, the squares of which, 4 and 9, have no common measure. It is owing to the incommensurability of quantities, that it is found so difficult to explain the doctrine of proportion in the elements of geometry.

INCOMPA'TIBLES. In Chemistry, salts and other substances are said to be *incompatible* which cannot exist together in solution without mutual decomposition. Thus the soluble salts of lead and of baryta are incompatible with sulphuric acid and the sulphates, because the sulphates of lead and of baryta are insoluble, and consequently thrown down in the form of precipitates.

INCOMPRE'SSIBILITY. That quality of bodies in virtue of which their volumes cannot be diminished. There are no substances, perhaps, absolutely incompressible. Liquids, however, resist compression with great force; but the experiments of Canton have proved that water has its bulk sensibly enlarged by withdrawing the pressure of the atmosphere. Nevertheless the extent to which the compression can be carried is very small. On enclosing water within an iron cannon, the sides of which were three inches in thickness, and applying a very great force of pressure, the cannon burst before the volume of water had been reduced to 19-20ths of its original dimensions. A pressure equal to that of the atmosphere reduces the bulk of water only about 48 parts in one million.

I'NCREMENT (Lat. *increase*), in the higher Mathematics, denotes a small but finite increase of a variable quantity. It is the difference between two successive values of the function of a quantity increasing according to a determinate law. *The method of increments* was the name given by Dr. Brook Taylor to a method of analysis invented by him, and which has since been extensively cultivated under the appellation of the *calculus of finite differences*. It is of great use for the summation of series, and furnishes an easy and rapid solution of a great variety of difficult problems to which other means of investigation would hardly apply. *Taylor's Methodus Incrementorum* was published in 1715, and contained the celebrated theorem which has since been made the basis of the differential calculus. (See *Euler's Calculus Differentialis;* Bossut, *Calcul Différentiel et Intégral;* Lacroix's large work; and Sir J. Herschel's Essay in the Appendix to the Cambridge translation of *Lacroix's Differential and Integral Calculus*.)

Increment, in Rhetoric, is a species of climax rising gradually from the lowest to the highest. *See* Climax.

INCRUSTA'TION. (Fr.) In Architecture and Sculpture, a work fixed with cement or cramp irons into notches made to receive it; such as inlaid work and mosaics, &c.

INCUBA'TION. (Lat. incumbo, *I brood over.*) Hatching, or the lying down of an animal upon her own or another's eggs, communicating to them, and maintaining them at, her own temperature: a condition essential to their development. In many animals the development of the fœtus takes place after the exclusion of the egg, and whilst it is maintained in contact with the external surface of the parent's body, as in the crab and lobster tribes, beneath the caudal plates; or agglutinated to the surface of the abdomen, as in certain species of pipe-fish (*Syngnathus*); or concealed in cutaneous marsupial cavities, as in other species of *Syngnathus*, and the *Hippocampus;* but in these and other instances from the cold-blooded animals, the protection of the ova seems to be the object of their attachment to the parent, and not the communication of warmth or any other influence essential to their development. It is only in the Oviparous class with warm blood, or birds, that true incubation takes place, and in this class without any exception. Another characteristic of true incubation is that the place of the eggs determines that of the incubator, which can only perform its office by *lying down upon the eggs;* while in most of the examples of false incubation in the cold-blooded animals, the eggs are retained by special contrivances in contact with the parent, without occasioning any restraint upon her postures or movements.

That a due degree of warmth is the essential object of incubation in birds, is proved by the ancient and well-known practice of substituting artificial heat, by which fertile eggs are hatched in the same period, and the excluded chick is as fully and strongly developed, as when produced by natural incubation. (See *infra*.)

The mean temperature of incubation is 100° Fah.; it may vary from 95° to 105°, and towards the close of the process, may be suspended for one or two hours, or for a longer period, according to the degree of extraneous heat which the eggs may derive from their situation, without fatal consequences to the embryo.

The power of communicating the requisite degree of warmth to their eggs arises out of the unusual development of, and determination of blood to, a peculiar plexus of vessels distributed over the skin of the abdomen, and which, in most birds, is connected with a derivation of blood from the internal organs of generation, after the subsidence of the functional activity of the ovarium and oviduct, to the external integuments. The vascular, hot, and sensitive condition of the skin of the abdomen is the exciting cause of that uncontrollable propensity to incubate which the Greeks denominated "storge," and which, with its associated phenomena of patience, abstinence, and self-denial, forms so remarkable a feature in the economy of birds. The egg of the bird presents several peculiarities in relation to the circumstances under which it is to be developed: its oval form permits a greater proportion of its surface to be in contact with the heat-communicating skin of the parent than if it had been a spherical body; while the shell, by virtue of its hard calcareous texture, and its arched disposition about the soft contents, sufficiently defends them from the superincumbent pressure. As warmth is the only essential influence which the egg derives from the parent, the shell is porous, and permeable to air, and the germ is surrounded by an adequate store of nutritious matter. This matter is of two kinds: the external, called the white of the egg, or albumen, which wholly disappears during the process of incubation; and the internal part, or yolk, inclosed in a peculiar membrane, and rendered lighter and of an orange colour by the admixture of a peculiar oil. The germ is situated at the superficies of the yolk, beneath the vitelline membrane, in the circular opaque white spot called the "cicatricula," or "tread;" and a peculiar mechanism is superadded to the yolk by means of which the germ-bearing surface of the yolk is always kept uppermost and next the warmest surface of the egg, and at the same time is relieved from the pressure against the hard shell, to which it must have been subject if the light yolk had not been restrained from rising to absolute contact with that surface. Both these purposes are effected by the attachment of two cords of condensed albumen, continued at one end from near the poles of the yolk, but a little more distant from the germ-bearing side than the line of the transverse axis, and expanding at the opposite end, which is lost in the layers of albumen near the poles of the egg. Thus by their presence and place of attachment these cords, called the "chalazæ," restrain and regulate the rising of the yolk; so that whichever way an egg be turned, the larger proportion of the light yolk always rises above the attachment of the restraining cords, with the cicatricula upon its summit. The period of incubation is generally directly as the size of the bird, but the degree of development which the chick attains prior to exclusion varies. As a general rule, it is inferior in birds of flight, as the Accipitrine and Passerine orders, than in the terrestrial, wading, and swimming birds; and the warmth and complexity of the nest bears relation to this difference of development. If the thrush had been forewarned that her young would be excluded from the egg naked and helpless, she could not have prepared beforehand a warmer and more comfortable abode than her instinct had led her to construct for their accommodation; and if with such a nest we contrast the rude recess of straw in which the hen deposits and incubates her eggs, it might be imagined that she knew beforehand that her chickens would come into the world well clothed, and strong enough at once to run about and pick up their own food. In this case, therefore, the nest relates only to incubation; in the other to incubation and subsequent rearing of the young: and according to the degree of development attained during incubation, and the associated condition of the nest and habits of the parent, birds have been divided into two great groups, the *Aves altrices*, and *Aves præcoces*. *See* Avis.

Artificial incubation has been practised from a remote period by the Egyptians and Chinese; the former, indeed, have carried this process to such a high degree of perfection, as in many instances to have entirely superseded the use of the hen in hatching. It is effected either by means of an oven, stove, or steam, the principles of which will be found detailed in *Ure's Dictionary of Arts, &c.* This process has received considerable attention from the French philosophers; but perhaps the best exemplification of its results that has been witnessed in Europe is given by the *Eccaleobion*, which was lately exhibited in Pall Mall. This term, recently invented to express the process of artificial incubation, is derived from the Gr. ἐκκαλέω, *I call out* or *produce*, and βίος, *life*.

I'NCUBUS. (Lat. incubo, *I lie upon;* because the sufferer feels as if something pressed upon his chest.) The nightmare. The name incubus is derived from imaginary fiends or spectres, to whom strange powers are attributed by the writers on dæmoniacal agency. Many noble families were supposed to have their origin from the connection of incubi with females, as in the well-known instance of Robert of Normandy, called *le Diable*. (See *Encyc. Metr.*)

INCU'MBENT. (Lat. incumbo, *I lie upon, or occupy.*) A term applied to the holder of an ecclesiastical benefice.

INCUNA'BULA. (Lat. *a cradle.*) In Bibliography, a term applied to books printed during the early period

of the art: in general confined to those which appeared before the year 1500.

INCU'RVED. (Lat. incurvo, *I curve inwards.*) In Zoology, when a part is curved inwards.

INDECLI'NABLE. In Grammar, a word admitting of no declension or inflexion. Adverbs, prepositions, particles, conjunctions, are all indeclinable. In classical languages, indeclinable nouns are those few (chiefly borrowed by the Greeks and Latins from foreign languages) of which the termination is not altered in the several cases.

INDE'FINITE. In Botany, when stamens are above twenty in number: the word is applied to all other parts when their number is greater than can be readily counted. This term always refers in botany to number, and never to form

INDEFINITE PROPOSITION, in Logic, is one which has for its subject a common term, without any sign to indicate whether it is distributed or undistributed. *See* PROPOSITION.

INDEHI'SCENT (Lat. in, and dehisco, *I gape*), is said of a fruit the pericarpium of which continues perfectly closed, without opening in any degree when ripe.

INDE'MNITY. (Lat. in, *without*, and damnum, *loss.*) In Politics and Jurisprudence, a word of various significations, but applied usually to laws passed to relieve individuals from penalties to which they are liable in consequence of acting in an illegal manner. The Act of Indemnity, annually passed by the British parliament for many years prior to the repeal of the Test and Corporation Acts in 1828, was a measure for the relief of persons who had assumed any office without qualifying themselves for it by taking the oaths prescribed by those enactments. In Feudal Jurisprudence, the right of the lord to a certain duty payable by religious establishments to compensate him for the loss of those fines on alienation which would probably have accrued from time to time had their property remained in lay hands, was termed indemnity. In the language of modern politics, compensations paid by a state to other states, corporations, or individuals, for losses sustained through its acts, bear the same name. Acts of indemnity are also sometimes passed to relieve ministers from the responsibility of measures exceeding their strict constitutional powers, taken by them when parliament was sitting to meet some unforeseen public emergency, or in ignorance, it may be, that they had exceeded the powers vested in them by the constitution. In 1825 a law of indemnity was passed in France to compensate the losses sustained by the emigrants, their families, and those of persons who had been condemned to death for political offences in the course of the Revolution. The sum allotted to this purpose was an annual amount of 30,000,000 francs (about 1,200,000*l.*). A special commission was appointed to carry it into execution; but it appears that its labours were broken off before their completion by the political changes of 1830.

INDE'NTURE. In Law, a writing or deed comprising some contract between two or more parties. The name is derived from the ancient practice, according to which the original and counterpart original (to be retained by each party respectively) were written on the same skin of parchment, and then the two parts were separated by a notched or indented cut, so that when applied to each other they would appear to match. (*See* DEED.)

INDEPE'NDENCE, DECLARATION OF, in the History of the United States of America. The "Declaration of Rights" was adopted by the first general congress of the then revolted colonies, which met at Philadelphia in September, 1775. In this declaration that assembly asserted the right of internal legislation and taxation to be in the provincial legislatures, and declared various acts of the mother country to be infringements and violations of the rights of the colonists. The second congress, which met in May, 1776, adopted on July 4. of that year a declaration of independence; by which, after again recapitulating the grievances complained of in the former declaration, it declared the colonies to be free and independent states, absolved from all allegiance to Great Britain. The first draught of this famous declaration was prepared by a committee of five; consisting of Jefferson and Adams (both afterwards presidents), Franklin, and Sherman and Livingston. Jefferson and Adams were afterwards deputed as a sub-committee to prepare the declaration itself; but, in the shape in which it finally appeared, it was in fact the work of the former.

INDEPE'NDENTS. A Protestant sect; so called because they maintain that every single congregation of Christians which meet in any one place for public worship forms a church or independent religious society in itself, unconnected with, and not amenable to, any other church or congregation. They consequently condemn every thing like a national establishment of religion, whether episcopal or presbyterian; and insist that each congregation of Christians has inherent and indefeasible power in itself to exercise ecclesiastical government, to fix their own tenets and form of religious worship, and to adopt their own standard of church discipline, without being responsible to bishops, presbyteries, or synods, or even to the state itself. The Independents were not at any time, and are not at this day, remarkable for any peculiarity of religious creed. They have always maintained, speaking generally, Calvinistic doctrines; their only peculiarity consisting in their maintenance of independent ecclesiastical government.

Of the history of this sect it may be proper to give a brief account. On the reformation of religion in England, the great body of Protestants adopted, under the auspices of the government, the episcopal form of church polity, which was in consequence established as the national religion. But there were not a few who conscientiously thought that this polity too nearly resembled that which had been supplanted; and objected, besides, to the vestments adopted by the clergy in the celebration of divine worship, to the liturgy, and above all to the sign of the cross used in baptism, as unscriptural and erroneous. These non-conformists, or dissentients from the established faith, are known in history under the name of *Puritans*, as the followers of Novatian had been denominated in the third century. They were evidently so called in derision, in consequence of the superior purity and sanctity they assumed, and of the greater deference they showed to scripture authority, both as to doctrine and the form of religious worship. But while they forsook the national church, and condemned many of her tenets, they did not agree among themselves. They were, in truth, unanimous in nothing but in resisting the constitution of the predominant hierarchy. Some of them were in favour of presbytery, or ecclesiastical government vested in a gradation of church courts, such as Calvin had established in Geneva, and as Knox had introduced into Scotland. Others were against every form of state religion, or union of churches under the same ecclesiastical government; but regarded each congregation of Christians as being *jure divino* a complete and independent church, competent to judge, decide, and act for itself, without any external interference or responsibility whatever. Of this latter opinion, which constitutes the pure principle of English Independency, the author and great advocate was Robert Brown, who was originally a clergyman of the Protestant episcopal church, from which he seceded, and avowed his new doctrines about the year 1580. (*Neal's Hist. of the Puritans*, vol. i. ch. vi. London, 1822.) Brown is represented by Neal as a vehement and popular declaimer, and insinuating in his manners; and hence he succeeded in detaching many from the episcopal faith, and in establishing several separate churches. He not only advocated the leading principles of Independency as we have stated them above, but taught that the priesthood was neither a distinct order in the Christian church, nor conferred an indelible character; that every person regarded by the majority of a congregation as qualified to teach might be set apart for that office by the election of his brethren, and by imposition of their hands; in like manner, by their authority, he might be discharged from that function, and reduced to the rank of a private Christian. He also maintained that the right of the pastors to preach was not peculiar to them; on the contrary, that any member who thought proper to exhort or instruct the brethren enjoyed the inherent right of doing so, or of "prophesying" before the whole assembly. Hence it happened that after the stated pastor had finished his services, the ordinary members were allowed to communicate in public their sentiments on any religious subject. (*Ibid.*; and *Mosheim's Ch. Hist.* vol. v. 355-6. London, 1822.) But while Brown enforced these views, and claimed liberty of conscience to himself, he was not willing to allow similar privileges to other sects, particularly the Church of England. "The Brownists," for so the Puritans were now called, "did not differ from the Church of England in any articles of faith; but were very rigid and narrow in points of discipline. They denied the Church of England to be a true church, and her ministers to be rightly ordained. They maintained the discipline of the Church of England to be popish and anti-Christian, and all her ordinances and sacraments invalid. Hence they forbade their people to join with them in prayer, in hearing, or in any part of public worship; nay, they not only renounced communion with the Church of England, but with all other reformed churches, except such as should be of their own model." (*Neal*, i. 303.)

Brown and his followers, as they had imbibed such extreme views, cannot be expected to have been allowed to live undisturbed in the dark times to which we refer. He, in truth, suffered severely for his principles, both for some works he published, and for the ecclesiastical doctrines which he travelled throughout England in propagating. He was committed, as he afterwards boasted, to no fewer than thirty-two prisons in succession, in some of which he could not see his hand at noonday. Nor were his adherents more mercifully treated: many of them were fined and imprisoned, and some put to death. (*Neal*, i. 313.) Under these circumstances, a body of the party, with Brown at their head, fled to Holland,

and founded churches at Middleburg, Amsterdam, and Leyden. But these establishments were neither solid nor lasting. When the Brownists were delivered from the hands of the bishops their oppressors, they quarrelled among themselves; and their leader, weary of his office, returned to England in 1589, and not merely renounced the opinions which he had suffered so much in promulgating, but returned into the bosom of the church which he had abandoned, and which he had so long and so severely calumniated.

The Brownists that still remained in Holland, now left to their own discretion, and learning moderation from experience, were not unprepared to modify or reform the severity of the discipline of their founder. This judicious change was brought about by John Robinson of Norfolk, member of the congregation at Leyden; "a man who had much of the solemn piety of the times, and who, perceiving the defects that reigned in the discipline of Brown, and in the spirit and temper of his followers, employed his zeal and diligence in correcting them, and in modelling the society in such a manner as to render it less odious to his adversaries, and less liable to the just censure of those true Christians who looked on charity as the end of the commandments." (*Mosheim*, v. 359-60.) Hitherto the sect had been called Brownists: they now renounced that name, and have since been known under the title of Independents; and Robinson, who wrote an "Apology" (*Apologia justa et necessaria pro Exulibus Anglis, qui Brownistæ vulgo appellantur.* Lugd. Batav. 1619. 8vo.) for them, in which he gave a minute and systematic exposition of their principles, was considered as their founder. The Independents were much more commendable than the Brownists, particularly in the moderation of their sentiments and the order of their discipline. They laid aside that hostility to other sects which Brown had inculcated. They agreed with the reformed churches generally in articles of faith. They wished to maintain communion with them. They differed with them only on the subject of church government. They were also much more attentive than the Brownists had been to the establishment of a regular ministry in their communities; for, while the latter promiscuously allowed all ranks and orders of men to teach in public, and to perform the other pastoral functions, the Independents had, and still have, a certain number of ministers chosen respectively by the congregations where they are fixed. Nor is any person among them permitted to speak in public till he has received the sanction of the congregation. (*Ib.*; and *Mosheim*, ut supra.)

Independency, thus put on a more rational and Christian footing in Holland, was introduced into England by Mr. Henry Jacobs in 1616; an individual who established the first Independent or (as it is not inappropriately called) Congregational Church in this country. For some time, however, the sect made but slow progress in England. Its members concealed their principles from public view, to avoid the penal laws that were in existence against non-conformists. But during the latter part of the reign of Charles I., when, amidst the shock of civil and religious discord, the authority of the Episcopal Church began to decline, the Independents assumed greater courage, and publicly avowed their principles with a degree of confidence not previously exhibited by them. From this period their progress was rapid: a circumstance that may be imputed to a variety of causes, particularly the learning of their teachers, the unpopularity and declining state of episcopacy, and the support of Oliver Cromwell, who espoused their cause and enrolled himself among the list of their members. They probably were, during Cromwell's time, the most powerful and important religious body in England; though for a few years previously to the death of Charles I. the Presbyterians may be said to have had the ascendency. Indeed, presbytery had been established by act of parliament as the national church; and it was chiefly owing to the growing influence of the Independents that this act was rendered inoperative. (*Murray's Life of Samuel Rutherford*, chap. viii. Edinburgh, 1628.) Notwithstanding the "Apology" written by Robinson, which was regarded as containing the best summary of the principles of the sect, the Independents as a body had not agreed on any standard of faith and discipline; but, in the year 1658, their leading members held a meeting in London, under the sanction of the Protector, and passed "the Savoy Confession, or a Declaration of the Faith and Order owned and practised by the Congregational Churches in England, agreed upon and consented unto by the Elders and Messengers in their Meeting at the Savoy, Oct. 12. 1658." This Confession, and Robinson's "Apology," on which it is mainly founded, contain a synopsis of their various tenets; and from these it appears, as Mosheim remarks, "that they differed from the Presbyterians or Calvinists in no single point of any consequence, except that of ecclesiastical government." (*Adam's Religious World Displayed*, ii. 312-13.)

Thus matters stood at the date which we have just specified. What might have been the issue of the struggle between the Independents and Presbyterians if Cromwell had lived, or if the dynasty which he established had lasted, cannot be told. But the restoration of Charles II., and with him the episcopal church, put an end to the influence of both sects. The Act of Uniformity was passed in 1662; the object of which was to crush non-conformists, particularly the Independents and Presbyterians. The Act required from clergymen a direct recognition of the principle of episcopacy. The effect of this was the retirement of about 2000 clergymen from their respective churches—Independents, Presbyterians, and Baptists; whom Dissenters still characterize in history as "the illustrious two thousand," the ejected members," or "the Bartholomew worthies." The Independents, however, though proscribed, still subsisted; but in a state of persecution, dejection, and weakness. But the Revolution of 1688, and the Act of Toleration, which was passed in the subsequent year, brought them peace and the free exercise of their religion. They were now a small body as compared with the Presbyterians; but the two sects, having much in common, and differing only as to church government, entered into an association with each other, under certain heads of agreement, which tended to the maintenance of their respective institutions. (*Whiston's Memoirs of his Life and Writings*, vol. ii.; *Mosheim*, v. 361-63.)

Since the period of the Revolution, the Independents have greatly increased both in numbers and importance. The extraordinary revival of religious zeal which took place about the middle of last century, under the influence of the two Wesleys and Whitfield, was of essential service to the sect of which we are treating. Many other persons, awakened to a deeper sense of religion, refusing to unite with any of the three bodies of Methodists, the Wesleyan, the Whitfieldian, or the Countess of Huntingdon's, joined the Independents, and formed numerous churches in connection with that sect. The Independents have long ago withdrawn from their association with the Presbyterians, or indeed with any body of Dissenters, and act by themselves. They are distinguished from all other Protestant communities chiefly by the two following circumstances:—*First*, They reject the use of all creeds and confessions (including the Savoy Confession and Declaration) drawn up by fallible men; requiring of their teachers no other test of orthodoxy than a declaration of their belief in the gospel of Jesus, and their adherence to the Scriptures as the sole standard of faith and practice. *Second*, They attribute no virtue whatever to the rite of ordination; for they declare that the qualifications which constitute a regular minister of the gospel are a firm belief in the Bible, fervent piety, a desire for the glory of God and the salvation of mankind, a competent stock of knowledge, and an initiation to the pastoral charge from some Christian congregation. These two circumstances constitute the distinguishing characteristics of the Independent denomination. They do not believe, as may also be mentioned, that an imposition of the hands of bishops or presbyters at ordination confers any new power or prerogative; though it is their custom to impose hands in inducting a pastor to a particular charge as a token of recognition in a new relation. In point of religious doctrine they vary from the high Calvinism of the Savoy Confession; though moderate Calvinism is maintained, speaking generally, by both pastors and people. The Independents teach that every point both of doctrine and church discipline is vested exclusively in the congregation, and that whatever is supported by a majority must necessarily be law. They do not think it imperative to assemble synods; yet if any such be held, which they are periodically, they look on their resolutions as prudential counsels; but not as decisions to which they are obliged to conform. (*Adam's Rel. World Displayed*, ii. 314.)

Of the extent and influence of the Independents in England a pretty correct idea may be formed from the number of their colleges or academies, and of their chapels. These colleges or academies are exclusively confined to the education of ministers belonging to their own denomination. Some of these institutions are wealthy endowments: others of them are supported by annual subscriptions. Their number is ten; the oldest of which is at Homerton, Middlesex, which was founded in 1730. The last established college is at Manchester, which was instituted in 1837. The others were founded at different intermediate dates. The number of Independent chapels in England in 1829, according to the *Congregational Magazine* for the year 1829, was 1683; but that number is now understood to have been increased to upwards of 1700. In Scotland the Independents have 95 chapels, and in Ireland about 30; but it is reckoned that they have no fewer than 1000 congregations in the United States.

INDETE'RMINATE. In Mathematics, quantities which change their values are said to be *indeterminate*, in opposition to those whose values remain fixed and invariable. For example, in the equation of the ellipse

$b^2 x^2 + a^2 y^2 = a^2 b^2$, the co-ordinates x and y are indeterminate, while the axes a and b are constant, quantities.

INDETERMINATE. In Botany, when a stem is never terminated by a flower, nor has its growth stopped by any other organic cause: example, *Veronica arvensis*.

INDETE'RMINATE ANA'LYSIS, is a branch of Algebra which has for its object the investigation of problems which admit of an infinite number of different solutions. When the enunciation of a problem furnishes a less number of equations than there are unknown quantities, the problem is indeterminate in this sense,—that the equations may be satisfied by assigning to the unknown quantities an infinity of different values. It happens, however, in the greater number of cases, that the nature of the question requires the values of the unknown quantities to be expressed in whole and positive numbers; a condition which greatly restricts the number of solutions.

As in the ordinary algebraic analysis, problems belonging to the indeterminate analysis are of the first or second degree, according as the simple powers or squares of the unknown quantities enter into the equations expressing their conditions. Every equation of the first degree, containing two unknown quantities, may be reduced to the form $ax + by = c$; and it is plain that if only one equation of this sort is given, the values of x and y are wholly indeterminate, for any value whatever may be given to one of these quantities, and it will be easy to find a value of the second which will satisfy the equation. In the indeterminate analysis, the object is to find all the values which x and y can have in whole numbers; the constants a, b, and c denoting whole numbers, either positive or negative.

For example, let it be proposed to divide the number 159 into two parts, one of which is divisible by 8, and the other by 13. If we denote by x and y the quotients of the required parts, divided respectively by 8 and 13, these parts themselves must be $8x$ and $13y$; consequently the problem is expressed by this equation,

$$8x + 13y = 159 \ldots. (1.),$$

and it will be solved when x and y are expressed by whole positive numbers.

In the first place, this equation gives $x = \frac{159 - 13y}{8}$, or $x = 19 - y + \frac{7 - 5y}{8}$; but as x and y must be whole numbers, it is obviously necessary that $\frac{7 - 5y}{8}$ be also a whole number. Suppose this to be n; we have then $\frac{7 - 5y}{8} = n$; whence $5y + 8n = 7 \ldots. (2.)$, an equation of the same form with (1). The value of y deduced from this is $y = \frac{7 - 8n}{5}$ or $y = 1 - n + \frac{2 - 3n}{5}$. Now, precisely in the same manner as before, since y and n are whole numbers, $\frac{2 - 3n}{5}$ must necessarily be a whole number. Suppose this to be n', and we have $\frac{2 - 3n}{5} = n'$; whence

$$3n + 5n' = 2 \ldots. (3.)$$

From this last equation we get $n = \frac{2 - 5n'}{3}$, or $n = -n' + \frac{2 - 2n'}{3}$. Continuing the same process, we now make $\frac{2 - 2n'}{3} = n''$ (where n'' must be a whole number), whence $2n' + 3n'' = 2 \ldots. (4.)$;

from which we obtain $n' = \frac{2 - 3n''}{2}$, or $n' = 1 - n'' - \frac{n''}{2}$. Suppose, next, $\frac{n''}{2} = n'''$, and there results

$$n'' = 2n''' \ldots. (5.)$$

Thus at last an equation has been found which is satisfied by making n''' equal to any whole number whatever; and, on attending to the different steps of the process, it will readily be observed that x and y, and the indeterminate quantities n, n' n'', n''', are connected by the following system of equations:—

$$\begin{aligned} x &= 19 - y + n \\ y &= 1 - n + n' \\ n &= 0 - n' + n'' \\ n' &= 1 - n'' - n''' \\ n'' &= 2n'''. \end{aligned}$$

On deducing from these equations the values of x and y in terms of n''', we find $x = 15 + 13n'''$, and $y = 3 - 8n'''$. Now, on making n''' successively equal to 0, 1, 2, 3, &c., or equal to −1, −2, −3, &c., these two equations will give all the values of x and y in whole numbers, whether positive or negative, by which the equation $8x + 13y = 159$ can be satisfied. But if, as the conditions of the problem require, we take account only of the positive solutions, the values of n''' must be so assumed that the expressions $15 + 13n'''$ and $3 - 8n'''$ are both positive; and it is manifest that this can only be done by assuming $n''' = 0$, or else $n''' = -1$, for all other numbers substituted for n''' render the one or the other of these two expressions negative. If we make $n''' = 0$, we obtain $x = 15,\ y = 3$;
and if we make $n''' = -1$,

$$x = 2,\ y = 11;$$

and either of these two systems of values verifies the proposed equation.

The preceding example will show, more distinctly than perhaps any rule would do, the general methods employed to solve indeterminate algebraic problems of the first degree. With regard to equations of the second degree, the difficulties of solution are infinitely greater, and in fact involve some of the most abstruse theories of algebraic analysis. The subject is discussed at length in *Legendre's Théorie des Nombres*.

The oldest treatise on the subject of the indeterminate analysis is the *Arithmetic* of Diophantus of Alexandria, the best edition of which is that of Toulouse, 1670; with a *Commentary* by Bachet, and notes by the celebrated Fermat. On the revival of the mathematical sciences, the subject was extensively cultivated by Fermat, Descartes, Wallis, Lord Brounker, and others. One of the most luminous elementary treatises on the subject is contained in the second volume of *Euler's Algebra*.

INDETERMINATE COEFFICIENTS. A method of analysis invented by Descartes, and of very extensive application in the higher mathematics. The principle of the method of indeterminate coefficients consists in this, that if we have an equation of this form,

$$A + Bx + Cx^2 + Dx^3 + \&c. = 0,$$

in which the coefficients A, B, C are constant quantities, and x a variable which may be supposed as small as ever we please, each of these coefficients, taken separately, is necessarily equal to zero: that is to say, we must always have $A = 0$, $B = 0$, $C = 0$, &c., whatever may be the number of terms of the given equation.
